4 Abstract

5 Urbit's networking protocol was redesigned
6 achieving over 100× throughput improvements while
7 implementing content-centric networking in a produc-
8 tion peer-to-peer system. Unlike address-based routing,
9 all network operations (queries and commands) are ex-
10 pressed as remote namespace reads. Urbit's immutable
11 scry namespace enables efficient caching, determin-
12 istic encryption, and stateless publishing, while a
13 pre-distributed PKI eliminates handshake overhead for
14 single-roundtrip transactions. Lockstep Streaming, a
15 novel scale-invariant packet authentication scheme
16 using binary numeral trees, maintains authentication
17 integrity across variable MTU sizes at relay hops. The
18 Lackman traversal pattern enables constant-space
19 streaming authentication. Directed routing simplifies
20 peer discovery and NAT traversal compared to previous
21 approaches, while source-independent routing mini-
22 mizes relay state. Begun in 2023 under the auspices
23 of the Urbit Foundation and deployed in early 2025,
24 Directed Messaging represents the first large-scale
25 deployment of content-centric networking.

63 1 Introduction

64 The Directed Messaging project was a fundamental overhaul
65 of Urbit’s networking stack. It rewrote the protocol defini-
66 tion and the protocol implementation, split between Hoon code
67 inside Arvo (the Urbit overlay OS), and C code in Vere (the
68 Urbit runtime).¹ Directed Messaging addressed several major
69 limitations of Urbit’s previous networking stack: it increased
70 throughput by over 100×, improved peer discovery reliabil-
71 ity, enabled the scalability of content delivery, and introduced
72 a modular internal architecture that reduced implementa-
73 tion complexity. Directed Messaging is an encrypted, authenticated,
74 peer-to-peer, packet-switched, message-oriented, connection-
75 less, content-centric, transactional network protocol with its
76 own congestion control, transmission control, and packet-level
77 authentication. It was deployed to the Urbit network in early
78 2025.

79 These improvements were driven by Directed Messag-
80 ing’s total adherence to a request-response discipline through-
81 out the stack, bundled with heavy use of Urbit’s immutable
82 referentially-transparent global namespace, called the “scry
83 namespace”. Every network message is either a request for
84 data at a “scry path” (Urbit’s equivalent of a URL), or an au-
85 thenticated response that includes the data at that path. This
86 is true at the message layer and the packet layer, and for both
87 reads (queries) and writes (commands).

88 Before Directed Messaging, the bandwidth Urbit was able

¹The original Ames protocol is described in early detail in the Urbit whitepaper (~sorreg-namtyv et al., 2016) with further elaboration in ~rovnyx-ricfer, “Eight Years After the Whitepaper”, *USTJ* vol. 1 iss. 1, pp. 1–46.

89 to utilize was extremely limited, maxing out in the hundreds of
90 kilobytes per second. It lacked orders of magnitude of perfor-
91 mance in order to make effective use of commodity network-
92 ing hardware, such as on a laptop or cloud instance. With Di-
93 rected Messaging, Urbit’s networking speed was able to reach
94 over 1 Gbit/s on commodity hardware, sufficient for the vast
95 majority of contemporary personal use cases.

96 Directed Messaging managed to improve throughput while
97 preserving Urbit’s already-good latency performance. For
98 small messages, a network transaction is accomplished in one
99 roundtrip: a command sent one way, followed by an acknowl-
100 edgment the other way. Due to Urbit’s public key infras-
101 tructure (PKI) being disseminated to all nodes *a priori* from a
102 Byzantine fault-tolerant source (the Ethereum blockchain and
103 a bespoke L2 for economic efficiency), no cryptographic hand-
104 shake is needed for two Urbit nodes (called “ships” in Urbit
105 lingo) to begin communication – even their first exchange is a
106 single roundtrip.

107 In addition to performance improvements, Directed Mes-
108 saging scales better by leveraging runtime caching to dissemi-
109 nate data to many clients simultaneously. This strategy is par-
110 ticularly effective within Urbit’s immutable scry namespace.
111 Directed Messaging also introduces a new procedure for peer
112 discovery and routing that is much more reliable and perfor-
113 mant than the previous setups. It deals better with NAT trav-
114 sal and with using supernodes as relays more efficiently and
115 reliably.

116 All of this is done by simplifying the basic network-
117 ing structure to enforce a rigid request-response discipline
118 throughout the entire system. In addition to that, it also places
119 all network messages, including acknowledgments and com-
120 mands, in addition to responses for queries asking for data, into
121 the referentially transparent scry namespace. This makes Ur-
122 bit’s entire networking stack a named data networking system,
123 which is also called content-centric networking. As far as the
124 authors know, Directed Messaging is the very first production
125 deployment of a content-centric networking protocol, as well
126 as the deployment with the largest number of nodes. Not only
127 that, its content-centricity preserves the immutability of Ur-

128 bit’s namespace throughout the stack. The immutability is key
129 to the scalability improvements and reliability improvements,
130 and it also helps with single-threaded performance.

131 Along the way, we designed and implemented a novel
132 scheme for streaming packet authentication. This helps pre-
133 vent denial-of-service attacks that could forge individual pack-
134 ets and spoof them in order to invalidate a large download.
135 This attack is prevented by authenticating every packet, but
136 unlike the previous version of Urbit’s networking stack, which
137 authenticated each packet with a signature (meaning one sig-
138 nature for every kilobyte of data, which was extremely ineffi-
139 cient), there’s only one signature per message. A Merkleiza-
140 tion scheme using binary numeral trees (TODO: cite) is used
141 to authenticate the packets within that message.

142 This achieves a property that, to our knowledge, has not
143 been demonstrated in prior packet authentication schemes:
144 the ability to handle a different maximum transmission unit
145 (MTU) at each hop in a relay chain without losing packet-level
146 authentication. It is a scale-invariant packet-authentication
147 scheme, and it also has good memory use characteristics, due
148 to a novel algorithm based on the “Lackman” scale-invariant
149 tree-traversal pattern developed by the authors. A relay re-
150 ceiving packets of one size and emitting packets of another size
151 only needs to hold one large packet in memory while stream-
152 ing (e.g. if receiving 1 kiB packets and sending 16kiB pack-
153 ets, it only needs to store 16 kiB of packet data at a time). It
154 can seamlessly handle any MTU that is one kilobyte, two kilo-
155 bytes, or any power-of-two number of kilobytes above that, up
156 to 128 MiB.

157 Another advantage of the Directed Messaging protocol is
158 that much more of the logic can be offloaded from the Urbit
159 operating system, Arvo, into the runtime. This enables de-
160 coupling between the formal specification, which is written in
161 Nock, and implementation, which is written in C. This is in
162 keeping with the spirit of Urbit’s “jet” system that separates
163 mechanism and policy for code execution. The most straight-
164 forward advantage of this decoupling is that each packet can
165 be processed ephemerally, without incurring a disk write as in
166 previous versions of Urbit’s network protocol – that was a se-

167 vere bottleneck on the maximum throughput. The implemen-
168 tation in the runtime could be swapped out with another im-
169 plementation written in another language, the congestion con-
170 trol algorithm could be swapped out, and parallelism strategies
171 could readily be employed to increase multicore CPU utiliza-
172 tion. The implementation that was deployed contains a major
173 optimization: specialized arena allocators to reduce memory
174 management overhead.

175 2 High-Level Protocol Design

176 2.1 Request/Response, Namespace Reads

177 The protocol design is based off the idea of a remote names-
178 pace read, wherein a “subscriber” ship requests data from a
179 “publisher” ship, and the publisher sends that data as the re-
180 sponse. The publisher ship makes the data available over the
181 network by assigning it a path in Urbit’s scry namespace and
182 setting permissions appropriately (permissioning will be de-
183 scribed fully in a later section). The subscriber ship, then, can
184 download data from another ship by sending it a request for
185 the data at a path and waiting for the response.

186 A network roundtrip is conceived of as a request, followed
187 by a response. The request consists of a “scry request”, i. e.
188 a request for data at a scry path. An example scry path is
189 `/~zod/1/2/c/x/~2025.9.22/sys/kelvin`. A scry path immutably
190 names a datum, in this case the `sys.kelvin` file published by
191 `~zod` (at `riff=1` and `life=2`), within the `%c` kernel module
192 (Clay, the revision control system), with request type `%x` (re-
193 quest file contents), and with timestamp at the start of the day
194 on September 22, 2025. When a ship receives a scry request
195 over the network, it can respond by sending a “scry response”
196 containing the datum bound to that path.

197 Over the network, a network request is a single UDP packet
198 that encodes a scry path, limited to 384 characters so the re-
199 quest packet always fits into the internet-standard 1500-byte
200 MTU (maximum transmission unit). A scry response may con-
201 sist of a single packet, or multiple packets, depending on the

202 size of the datum bound to that path. If the datum is 1kiB or
203 less, the response is encoded into a single UDP packet. Otherwise,
204 the first scry response packet contains only the first
205 1kiB of the datum, along with a fixed-width field containing
206 the number of bits in the whole datum.

207 If the subscriber ship receives a response indicating the da-
208 tum is multi-packet, it switches modes and begins requesting
209 the remainder of the datum, one kiB at a time. Each request for
210 a kiB of data is itself a fully-fledged namespace read request,
211 where the path in the request contains the path of the whole
212 datum as well as the chunk size being requested (configured to
213 1 kiB over the public internet, but this could be increased to any
214 power of 2 kiB's up to 128 MiB, for other environments, such
215 as intra-datacenter). The protocol definition does not require
216 those fragment requests to be sent in any particular order or
217 according to any particular congestion control algorithm. The
218 current implementation uses a packet-switched variant of the
219 TCP NewReno congestion control algorithm, written in C in
220 Urbit's runtime, to manage multi-packet reads. The message-
221 level authentication is sent in the first response packet. Each
222 subsequent packet is authenticated as being part of that mes-
223 sage by using the LockStep streaming authentication scheme,
224 described in a later section.

225 This remote read flow is a “pure read”: handling a read re-
226 quest does not require the publisher ship to change any persis-
227 tent state. But a general-purpose network protocol needs to be
228 able to express commands, not just reads. Directed Messaging
229 builds commands out of reads. A command is conceived of as
230 two reads, one in each direction:

- 231 1. The ship sending the command makes the command da-
232 tum available within its own scry namespace, so the re-
233 ceiving ship has the ability to read the command by send-
234 ing a remote read request.
- 235 2. The ship that receives the command, after attempting
236 to execute the command, makes the command's result
237 available within its namespace, so the sending ship has
238 the ability to read the result (hereafter called the “ack”)

239 by sending a remote read request. A result can be suc-
240 cess (“ack”) or an error datum (“naxplanation”, named
241 after “nack” for negative acknowledgment).

242 This approach is conceptually clean but immediately
243 presents two practical challenges. The first is triggering: how
244 does the receiving ship *know* to request the command datum
245 from the sending ship? There are many ships on the network;
246 it would be absurdly impractical to send requests to all of them
247 on the off-chance that one or two of them have an outstanding
248 command for us. The second challenge is latency: a naive im-
249 plementation would imply every command requires two net-
250 work roundtrips, one to remote-read the command and one
251 to remote-read the command’s result (ack or naxplanation).
252 If so, that would be unfortunate, since Urbit’s previous net-
253 working required only one roundtrip for a command and ack,
254 in the common case of a small (≤ 1 kiB) command datum, and
255 unneeded roundtrips are anathema to a good user experience
256 (Cheshire, 1996).

257 Fortunately, we can solve both problems with one weird
258 trick. We add a “request type” bit to each network request
259 packet indicating whether it is a read or a command, and if
260 it is a command, it includes not only the scry request path, but
261 also a scry response containing the first 1 kiB of the command
262 datum. When the receiving ship’s runtime receives the packet,
263 it looks at the ‘request-type’ bit to determine how to handle the
264 packet.

265 If the incoming request packet is a read, the runtime per-
266 forms a read request on the Arvo OS by firing its `+peek` arm,
267 a Nock function that reads from Arvo’s namespace. This read
268 request does not trigger any disk writes and could be run in
269 parallel with other reads and with an Arvo event. The runtime
270 then encodes the result of this read as a scry response packet
271 and sends it back to the IP and port that sent the request.

272 If the packet is a command, the runtime injects the packet
273 as a stateful Arvo “event” by firing its `+poke` arm (a Nock func-
274 tion that sends an event or command for Arvo to process, pro-
275 ducing effects and a new Arvo OS with a modified state). When
276 this event completes, one of the effects it produces can be a

277 scry response packet containing the ack, which the runtime
278 will send back to the IP and port that sent the request.

279 If the command datum fits within 1 kiB, the entire com-
280 mand is sent in the first packet, recapturing the single-
281 roundtrip flow for a command and an ack. Multi-packet com-
282 mands are downloaded by the commanded ship using the same
283 congestion control as downloading any other potentially large
284 datum – and, importantly, those incremental downloads do not
285 necessarily trigger unnecessarily frequent disk writes.

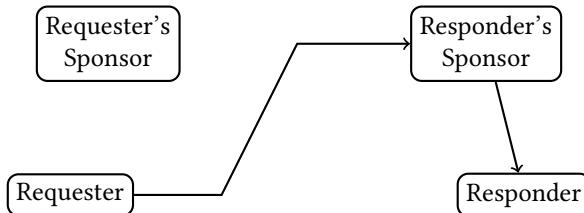

286 3 Routing

287 3.1 Directed Routing

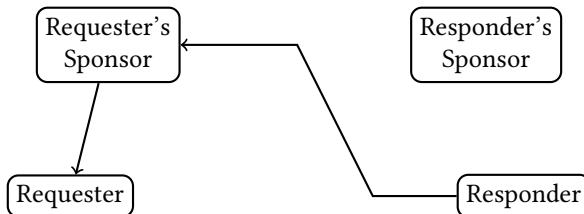

288 The Directed Messaging protocol gets its name from its rout-
289 ing scheme, which treats each bidirectional communication be-
290 tween two Urbit ships as directed, like a directed edge in a
291 graph. For each request/response roundtrip, one ship is the
292 requester, and the other is the responder, and that distinction
293 is known at every layer of the system. Making this direction-
294 ality known to routing enables a routing paradigm where a re-
295 sponse packet traces the exact same relay path through the net-
296 work as the request path, in the reverse order. Previous Urbit
297 networking protocols used the opposite paradigm: “criss-cross
298 routing”, so-called because both request and response could be
299 routed through the destination ship’s “sponsor”, i. e. the su-
300 pernode ship (“galaxy” root node or “star” infrastructure node)
301 responsible for relaying packets to that ship. In contrast, in di-
302 rected routing, the request and the response both use the same
303 relay: the responder ship’s sponsor. See Figure 1 for a compari-
304 son of the two routing strategies.

305 3.2 Relaying

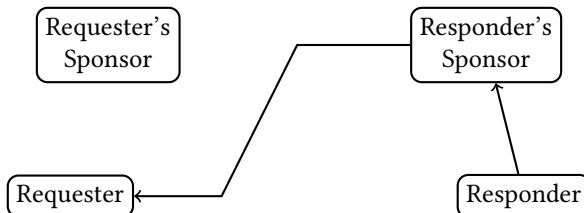

306 Making the directedness of communication legible to relays
307 and Urbit runtimes allows the protocol to be a faithful, if Urbit-
308 specific, Named Data Networking (NDN) protocol, which had
309 been Urbit’s stated goal since 2010. A Directed Messaging re-

(a) Request (same for both directed and criss-cross routing).

(b) Response (criss-cross routing).

(c) Response (directed routing).

Figure 1: Routing strategies.

310 quest packet acts as an NDN “interest” packet, and a response
311 packet acts as an NDN “data” packet.

312 The NDN family of protocols, created by Van Jacobson et al.
313 in the mid-2000s, differs from traditional networking protocols
314 in that an interest packet has no sender address field – the iden-
315 tity of the sender of a request is unknown to the network. In-
316 stead, a receiver (relay or server) remembers “where” it heard
317 the request from, and sends the response back to that. The no-
318 tion of “where” varies depending on the layer of the stack the
319 system is operating at: for an IP replacement, a relay would
320 remember the physical interface (e. g. Ethernet port) on which
321 it heard the incoming request. When building on top of IP and
322 UDP, as Directed Messaging does, a receiver remembers the IP
323 and port of the sender.

324 Previous Urbit network protocols still included the sender’s
325 Urbit identity in the request packets, failing to achieve the
326 “source independence” property that defines NDN. Directed
327 Messaging is completely source-independent for reads, and for
328 commands, it piggybacks a source-independent response onto
329 a source-independent request in such a way that the receiver
330 does know which Urbit address sent the request, but not in a
331 way that requires packet routing to know or use the source
332 Urbit address.

333 Source independence lets the routing operate fully locally,
334 i. e. without reference to or knowledge of anything beyond a
335 single hop away in either direction. This minimizes the data
336 storage and synchronization requirements for nodes, which
337 could become significant at scale.

338 Source independence entails stateful routing. Directed
339 Messaging adopts NDN’s Pending Interest Table, which stores a
340 mapping from each outstanding request to the IP and port that
341 sent that request. If the request times out (after roughly 30 sec-
342 onds), or the request is satisfied by a response, the request is
343 deleted from the table.

344 Since responses are authenticated down to the packet level,
345 and immutable (meaning no cache invalidation is ever needed,
346 only eviction), it should be straightforward for relays to cache
347 responses, enabling efficient content distribution through the
348 network. At present, each Urbit ship’s runtime has a cache for

349 its own responses, but supernodes (galaxies and stars) do not
350 yet cache responses from their sponsored ships.

351 3.3 Peer Discovery

352 Urbit is a peer-to-peer network. Only root nodes (galaxies) list
353 their own IP addresses publicly (on the Ethereum blockchain);
354 all other ships must be discovered on demand. When one ship
355 first sends a request to another ship, it generally doesn't know
356 at what IP and port that ship could be reached, and it also
357 doesn't know if the ship is reachable directly, or behind a fire-
358 wall and only reachable through its sponsor.

359 The criss-cross routing used in previous Urbit protocols
360 was hard to work with in practice and suffered from ineffi-
361 ciencies and bugs. Directed Messaging has a simpler approach
362 to peer discovery that is easier to reason about.

363 The main difficulties with criss-cross routing stem from the
364 structure of the internet. Most residential internet connections
365 live behind a firewall that blocks all unsolicited incoming UDP
366 packets. A laptop at home can send an outgoing packet to
367 some destination IP and port, and the router will relay response
368 packets back to the laptop for some time afterward, usually
369 30 seconds, as long as those response packets come from that
370 same destination IP and port.

371 A UDP-based peer-to-peer network, then, needs to include
372 not only residential nodes but also nodes on the public inter-
373 net, not behind firewalls. These nodes must be discoverable
374 so that residential nodes can ping them every 25 seconds, to
375 ensure the residential nodes can receive messages. In Urbit,
376 these public nodes are the galaxies (root nodes) and stars (in-
377 frastructure nodes). For now, only galaxies perform routing,
378 due to edge cases with two levels of supernodes in peer discov-
379 ery using criss-cross routing – we expect Directed Messaging
380 will unblock stars from participating in routing.

381 When communicating with another ship for the first time,
382 a ship first sends the packet to the other ship's sponsoring
383 galaxy, which has an open connection to its sponsored ship
384 if it's online. The galaxy receives a ping every 25 seconds from
385 its sponsored ship. Whenever the source IP and port change,

386 the galaxy’s runtime injects an Arvo event and its Arvo OS
387 saves the sponsored ship’s new location to disk.

388 In Directed Messaging, when the galaxy receives a packet
389 intended for one of its sponsored ships, it relays the packet.
390 This uses the pending interest table described above to track
391 the fact that there is an outstanding request that the galaxy
392 is expecting to be honored by a response from the sponsored
393 ship. The fundamental invariant of directed routing is that the
394 response packet must trace the exact same path through the
395 network as the request packet had, just reversed. Since this
396 request had gone through this galaxy, the response must also
397 route through the galaxy.

398 In Urbit’s previous protocols, in contrast, the response
399 would go directly from the sponsored ship back to the requesting
400 ship, and also potentially through the requesting ship’s
401 sponsoring galaxy. This works in principle, but one drawback
402 has to do with “route tightening” (described below): the re-
403 sponse route only tightens to a direct route (without relays) if
404 there are requests flowing in both directions; otherwise every
405 response will flow through the requester’s sponsor, even if the
406 requester is not behind a firewall.

407 3.4 Route Tightening

408 It is better for performance, scaling, and individual sovereignty
409 to obtain a direct route to another ship, rather than communi-
410 cating through relays. In order to facilitate this, the system
411 must automatically “tighten” a route over time to reduce the
412 number of hops. Directed Messaging accomplishes this in the
413 relay. When a relay receives a response packet (originally sent
414 by a transitively sponsored ship, but possibly through a relay
415 once stars begin relaying packets), it appends the IP and port
416 from which it heard that packet to the end of the packet be-
417 fore forwarding it to the requesting ship. Once the requesting
418 ship receives this augmented packet, it knows the address ap-
419 pended to that packet is next hop in the relay chain. Once it
420 knows that, when it sends packets to the responding ship, it can
421 send them through the first hop in the relay chain (the receiv-
422 ing ship’s galaxy), or to the next hop, which could be another

423 relay or the ship itself.

424 In the current implementation, the requesting ship uses a
425 simple procedure to decide which routes to send the packet
426 on. It tracks the date of the last received packet from both
427 the direct route and the route through the galaxy. A route is
428 considered active if a packet has been received on it within
429 the last five seconds. When the requesting ship goes to send a
430 packet, if the direct route is active, it sends the packet on that
431 route. Otherwise, it sends the packet through the galaxy and
432 also sends a copy of the packet on the direct route as a probe.

433 This ensures continuity of communication when switching
434 to or from a direct route, and it automatically tightens to the
435 direct route if the direct route is responsive and loosens to the
436 galaxy route if the direct route becomes unresponsive.

437 4 Authentication and Encryption

438 Directed Messaging is always authenticated and supports en-
439 cryption in a number of different modes:

- 440 • **Unencrypted reads:** A ship can publish data into its
441 namespace without encryption. Response messages are
442 signed using the ship's private key. The signature attests
443 to the scry binding: the pair of the scry path and the
444 datum at that path.
- 445 • **One-to-One Encrypted Reads:** A ship can make data
446 available to a single peer ship. Response messages are
447 authenticated via an external hash-based message au-
448 thentication code (HMAC) and internal signature. They
449 are encrypted using a symmetric key derived from the
450 Diffie-Hellman key exchange of the two ships' keys.
- 451 • **Commands:** Commands and their acks are both han-
452 dled as one-to-one encrypted reads.
- 453 • **One-to-Many Encryption:** A ship can make data avail-
454 able to many ships by sharing an encryption key for that
455 data to each ship using a one-to-one encrypted read. The

456 requesting ship then uses that key to encrypt the re-
457 quest's scry path and decrypt the scry response.

458 The core encryption primitives consist of:

- 459 • `kdf`: BLAKE3, in its key derivation mode.
460 • `crypt`: XChaCha8, with its 24-byte nonce derived by
461 processing the (arbitrary-length) input initialization vec-
462 tor (IV) using the key derivation function (`kdf`) with
463 "`mesa-crypt-iv`" as the context string.

464 Messages and their paths are encrypted separately. First, `kdf` is
465 used to derive an authentication key and encryption key from
466 the shared secret. The authentication key is used to compute a
467 128-bit keyed BLAKE3 hash of the path; this serves as the Au-
468 thenticated Encryption with Associated Data (AEAD) tag. The
469 encryption key is then used to encrypt the path with `crypt`,
470 using the tag as the IV. Concatenating the encrypted path and
471 authentication tag yields a “sealed” path. The message itself is
472 then encrypted with `crypt`, using the sealed path as the IV. Au-
473 thentication of the message is achieved via a Merkle hashing
474 scheme described later.

475 Directed Messaging’s encryption scheme uses a variant of
476 ChaCha20, XChaCha, with reduced rounds for performance.
477 XChaCha is an extended-nonce variant of ChaCha that accepts
478 a 192-bit nonce instead of the standard 96-bit nonce. However,
479 rather than using the caller-provided initialization vector di-
480 rectly as the nonce, Directed Messaging first applies a BLAKE3
481 key derivation function to derive a deterministic 24-byte nonce
482 from the IV using the context string "`mesa-crypt-iv`". This
483 XChaCha operation with 8 rounds then produces a derived key
484 and extended nonce, which are subsequently used for the ac-
485 tual ChaCha encryption (also with 8 rounds) of the message
486 payload. The use of 8 rounds instead of the standard 20 is a
487 performance optimization – ChaCha’s security margin allows
488 for this reduction in cryptographic applications where the ex-
489 treme paranoia of 20 rounds may be unnecessary (Aumasson,
490 2019), and the deterministic nonce derivation via BLAKE3 adds
491 an additional layer of domain separation.

Because the scry namespace immutably binds paths to their message data, the path serves as a synthetic IV for the message, making encryption deterministic. This solves multiple problems. It (along with other principles of Directed Messaging) prevents replay attacks by construction. Every Directed Messaging packet is idempotent at the application level (a duplicate packet can trigger a duplicate ack and minor state changes in the runtime and Arvo kernel related to routing state, but it cannot modify anything visible to an application). It further removes the need for explicit nonce management, such as generating, storing, and transmitting an explicit nonce for each message. Not tracking nonces reduces the system's security attack surface area considerably, since nonce state mismanagement is a common source of vulnerabilities. Finally, supporting encrypted values in the namespace allows the system to implement encryption using overlay namespaces (described in more detail below), which provide a clean layering that separates encryption from other concerns.

Before transmission, a single `0x1` byte is appended to the encrypted message, called a “trailer byte”. This solves a representation problem specific to Orbit’s atom system. In Orbit, data is ultimately stored as “atoms”: arbitrary-precision natural numbers. The atom system cannot distinguish between byte streams with equivalent numerical value; that is, it has no way to “say” `0x1000` instead of `0x1` or `0x1000000000` – all are numerically equivalent to `1`.² Thus, if a ciphertext happens to end with one or more zero bytes, those would be stripped when the ciphertext is represented as an atom, corrupting the data. Appending a `0x1` byte ensures that the atom representation always preserves the full length of the ciphertext, including any trailing zeros. During decryption, the code verifies that the final byte is indeed `0x1` (which catches truncation or corruption) and then strips it before decrypting. This construction provides authenticated encryption properties through the deterministic relationship between the IV and nonce, ensuring that any tampering with the ciphertext or IV will result in de-

²Note the relative most-significant byte (MSB) order notation used here, contrary to Orbit’s customary LSB order.

528 encryption failure.

529 4.1 Message Authentication and Encryption Details

530 4.1.1 Overlay Namespaces

531 Each of the three privacy modes has its own “overlay names-
532 space”, i. e. a part of the scry namespace that somehow trans-
533 forms values bound to a different part of the namespace. A
534 path in an overlay namespace often consists of a path prefix
535 containing the name of the overlay and any parameters needed
536 for the transformation it performs on the datum at the overlaid
537 path, followed by the overlaid path.

538 A handler function that deals with scry requests to the
539 overlay namespace is free to parse transformation parameters
540 out of the overlay prefix, inspect the overlaid path, make a scry
541 request for the data at that path, make scry requests related to
542 that path (such as existence checks for file paths), and run arbi-
543 trary code to transform the results. This is all possible because
544 scry requests are purely functional by construction – they are
545 deterministic functions of their inputs, with no hidden inputs,
546 and there is no mechanism by which they could change Arvo
547 state.

548 Directed Messaging uses overlay namespaces not only for
549 privacy modes, but also to publish individual packets within a
550 message. The packet’s size (expressed as the log base 2 kiB, e. g.
551 3 for 8 kiB or 4 for 15 kiB) and fragment number (index within
552 the message) are parameters to this overlay, which overlays the
553 message’s scry path.

554 Directed Messaging is the first Urbit kernel module to make
555 heavy use of overlay namespaces in its design. They play
556 an important role in maintaining boundaries between layers
557 within the system: privacy is separated, by construction, from
558 other concerns due to the isolation imposed by overlay names-
559 spaces. For example, an application can declare what privacy
560 mode it wants to use for a piece of data it publishes, and the
561 kernel enforces that by exposing it over the network using the
562 appropriate overlay namespace.

563 **4.1.2 %publ namespace (unencrypted public)**

564 Authentication: Ed25519 signature only (no encryption)

- 565 1. No encryption: The message data is jammed but not en-
566 crypted. The serialized response is sent in plaintext.
567 2. Signature authentication: A 64-byte Ed25519 signature
568 is computed over:

- 569 • The encoded beam path
570 • The LSS root of the unencrypted jammed data

- 571 3. Publisher's signing key: The signature uses the pub-
572 lisher's Ed25519 private key (extracted from their net-
573 working key).
574 4. Verification: The receiver verifies the signature using the
575 publisher's Ed25519 public key retrieved from Azimuth.

576 The %publ namespace uses unencrypted paths with the
577 structure:

578 `/publ/[life]/[path]`

579 in which `life` (key revision number) of the publisher's net-
580 working keys is used to identify which public key to use for
581 signature verification; and `path` is the actual user path in plain-
582 text. This is not encrypted and is visible to all network ob-
583 servers.

584 Everything in the %publ namespace is public: both the pub-
585 lisher's identity/key version and the content path are visible to
586 anyone. No encryption is applied to either the path or the mes-
587 sage payload. Authentication comes solely from the Ed25519
588 signature, which proves the publisher created this content. Key
589 rotation is supported through the life counter.

590 Its use cases include:

- 591 • Public data that should be readable by anyone
592 • Content where authenticity matters but confidentiality
593 doesn't
594 • Simpler than encrypted namespaces since no key ex-
595 change or group key distribution is required

596 4.1.3 %shut namespace (group encrypted)

597 In contrast, the %shut namespace is intended for one-to-many
598 encrypted data sharing, wherein a publisher ship shares data
599 with a group of ships by encrypting the data with a shared
600 symmetric key known to the group. The message is encrypted
601 with XChaCha20-8 using this group symmetric key. The key
602 is provided via the %keen task (not derived from ECDH). The
603 encrypted path indicates which group key to use. Signature
604 authentication takes place using a 64-byte Ed25519 signature
605 computed over the encoded beam path and the LSS root of the
606 encrypted data. The signature uses the publisher's Ed25519
607 private key, proving that the publisher created this encrypted
608 payload. The receiver verifies the signature using the pub-
609 lisher's Ed25519 public key from Azimuth, then decrypts with
610 the group key. In this security model, the signature proves au-
611 thenticity from the publisher, while encryption provides confi-
612 dentiality to group members. Anyone with the group key can
613 decrypt, but only the publisher can create valid signatures.

614 The %shut namespace uses encrypted paths with the struc-
615 ture:

616 /shut/[key-id]/[encrypted-path]

617 with the components:

618 1. **key-id**: A numeric identifier indicating which group
619 symmetric key to use for decryption. This allows mul-
620 tiple groups to be supported, each with their own key.

621 2. **encrypted-path**: The actual user path, encrypted using
622 the group key. This is sealed with the same symmetric
623 key used to encrypt the message payload, making the
624 entire scry path opaque to anyone without the group key.

625 The actual content path is hidden from network observers.
626 Only the key ID is visible in plaintext. The group key must be
627 obtained separately (typically via a %keen task) to decrypt both
628 the path and the message payload. Different groups using dif-
629 ferent key IDs can coexist without revealing which content is
630 being accessed.

631 4.1.4 %chum namespace (1-to-1 encrypted)

632 The %chum namespace is intended for one-to-one encrypted
633 data sharing between two ships. Authentication utilizes HMAC
634 only (without signatures). The message is encrypted with
635 XChaCha20-8 using a symmetric key derived from Curve25519
636 ECDH key exchange between the two ships' networking keys.
637 A 16-byte HMAC (BLAKE3 keyed hash) is computed over the en-
638 coded beam path and the LSS root of the encrypted data, using
639 the same ECDH-derived symmetric key. Both parties can inde-
640 pendently derive this key from their own private key and the
641 other party's public key. The receiver verifies the HMAC using
642 the shared symmetric key, then decrypts with the same key.
643 In this security model, the HMAC proves the sender possesses
644 the shared symmetric key (implicitly authenticating them as
645 the expected peer). No signatures are needed since only two
646 parties share this key. This applies to both pokes and acks.

647 The %chum namespace uses encrypted paths with structure:

648 /chum/[server-life]/[client-ship]/[client-life]/
649 [encrypted-path]

650 in which the components are:

- 651 • **server-life**: The life (key revision number) of the server
652 ship's networking keys, used to identify which version
653 of their keys to use for ECDH key derivation.
- 654 • **client-ship**: The @p address of the client ship in the
655 communication pair.
- 656 • **client-life**: The life of the client ship's networking keys,
657 used to identify which version of their keys to use for
658 ECDH key derivation.
- 659 • **encrypted-path**: The actual user path, encrypted using
660 the symmetric ECDH key derived from both ships' net-
661 working keys. This makes the scry path opaque to net-
662 work observers.

663 This arrangement yields some nice privacy properties. The ac-
664 tual content path is hidden from network observers. Only the

665 identities of both parties and their key versions are visible in
666 plaintext. Only the two ships involved can derive the sym-
667 metric key to decrypt the path and payload. Key rotation is
668 supported through the life counters.

669 **4.1.5 Other Cryptographic Properties**

670 Directed Messaging relies on the ability to rotate keys on chain
671 for its forward secrecy. Future versions of the protocol might
672 add a ratchet to minimize the damage if a private key is com-
673 promised.

674 **4.2 Packet Authentication**

675 One of the goals of Directed Messaging was to improve upon
676 the conservative safe-but-dumb “sign every 1 KiB packet” de-
677 sign of old Ames.³ The standard approach is to use asymmetric
678 crypto to establish a shared AEAD key, and use it to authenti-
679 cate each packet. This is just as safe as signing every packet,
680 and orders of magnitude faster. However, we still can’t verify
681 that a peer is sending us *correct* data until we’ve received the
682 entire message. They could send us 999 good packets and one
683 bad one, and we’d have no way of knowing which was which.
684 This is especially annoying if we want to download in parallel
685 from multiple peers: if the final result is invalid, which peer is
686 to blame? If we want to solve this problem, we need to get a
687 little more bespoke.

688 Verifying that a packet belongs to a particular message is
689 a job for a Merkle tree. So our protocol needs to split mes-
690 sage data into the leaves of a tree, and send both leaf data and
691 tree hashes. Early on, we debated whether to make these dis-
692 tinct request types; we settled on interleaving them. Now the
693 question becomes: which tree hashes do you need to send, and
694 when do you send them?

695 Our relevant design constraints were as follows:

³To wit, as first described in the Urbit whitepaper (~sorreg-namtyv et al., 2016).

- 696 • Sufficiently-small messages should not require more
- 697 than one packet.
- 698 • It should be possible to download in parallel.
- 699 • The protocol should be flexible with respect to the size
- 700 of a leaf.

701 An obvious first place to look for inspiration was Bao
 702 (O'Connor, 2018). However, Bao is not very amenable to being
 703 split into fixed-size packets: it intermingles leaf data and tree
 704 hashes into one stream, and the number of consecutive hashes
 705 varies based on the offset. You could modify it such that each
 706 packet consists of a leaf followed by at most one hash; indeed,
 707 this was the initial plan. Visually:

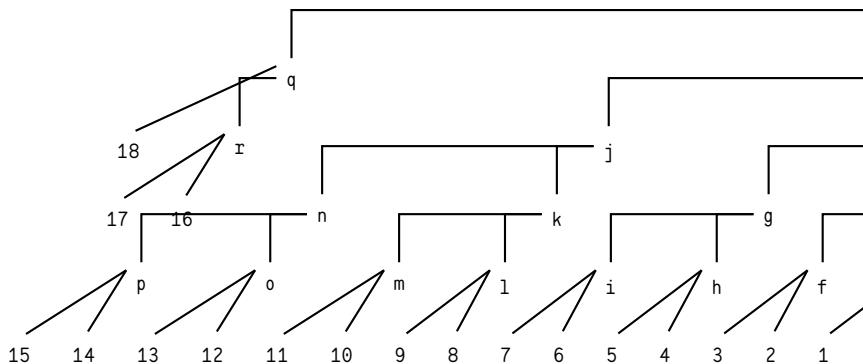

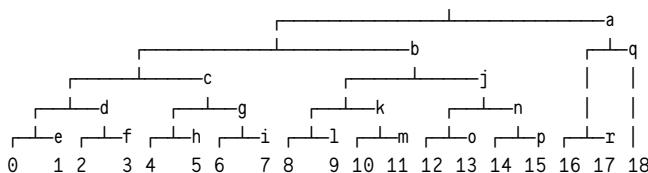

Figure 2: .

708 This is a binary numeral tree: a structure composed of
 709 perfect binary trees, imposed upon a flat sequence of bytes.

710 The numbers 0-18 represent leaf data (typically 1 KiB per leaf),
 711 while letters *a-r* represents tree hashes that are used to verify
 712 the leaves. So packet 3 would contain bytes 3072–4096 and leaf
 713 hash *d*.

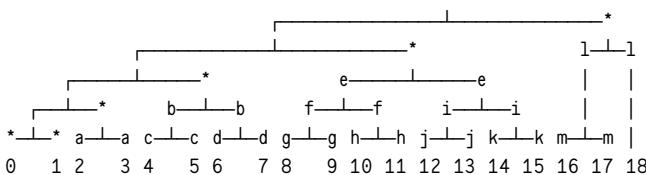

714 The main problem with this approach is that it requires
 715 buffering. In order to verify leaf 0, we need hashes *a* through
 716 *e* – five packets! Worse, once we've received five packets, we
 717 have the whole [0, 4) subtree, making hashes *d* and *e* redundant.
 718 (In BNTs, we use the notation [n, m) to refer to the perfect
 719 subtree containing leaves n through m-1.)

720 Buffering a few packets is not the end of the world, but the
 721 whole thing had kind of a bad smell to it. We asked: what
 722 would happen if we added another constraint?

- 723 • It should be possible to validate each packet as soon as it
 724 arrives, with no buffering.

725 For starters, an inescapable consequence of this constraint
 726 is that we must send the *full* Merkle proof for the first leaf
 727 before we can send the leaf data itself. Also, we can no longer
 728 send hashes that can't be immediately verified. For example, to
 729 verify *g*, we first need to have verified *c*; we can then combine
 730 *g* with its sibling hash and confirm that the result matches *c*.

731 While adding another constraint seems like it would make
 732 our life harder, in reality the opposite happened: the proto-
 733 col was greatly simplified. It turns out that by front-loading
 734 the initial proof hashes, we ensure that the received leaf data
 735 and hashes will never “run ahead” of what can be immediately
 736 verified. Here's what it looks like in practice:

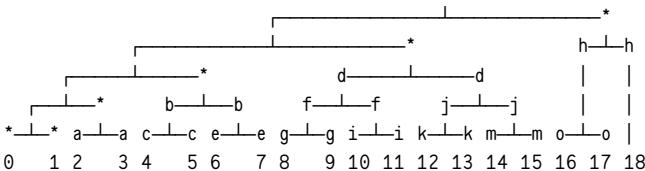

737 In the initial packet, we send the Merkle proof for leaf 0,
 738 i. e. all of the hashes marked with *. Each subsequent packet
 739 contains leaf data (leaf 0, 1, 2, etc.), and possibly a “pair” (*a*, *b*,

740 *c*, etc.), which comprises *both* child hashes under a particular
741 node. Packet-by-packet, the verifier sees:

```
742   Packet 0: Signed Merkle root + Merkle proof for leaf 0.  
743       Verify proof against signed root.  
744       We now have [0,1), [1,2), [2,4), [4,8), [8,16),  
745       and [16,19).  
746   Packet 1: Leaf 0 + Pair a.  
747       Verify leaf 0 against [0,1).  
748       Verify pair a against [2,4).  
749       We now have [1,2), [2,3), [3,4), [4,8), [8,16),  
750       and [16,19).  
751   Packet 2: Leaf 1 + Pair b.  
752       Verify leaf 1 against [1,2).  
753       Verify pair b against [4,8).  
754       We now have [2,3), [3,4), [4,6), [6,8), [8,16),  
755       and [16,19).  
756   Packet 3: Leaf 2 + Pair c.  
757       Verify leaf 2 against [2,3).  
758       Verify pair c against [4,6).  
759       We now have [3,4), [4,5), [5,6), [6,8), [8,16),  
760       and [16,19).  
761   ... and so on.
```

762 At each step, we “consume” two hashes (one to verify a leaf,
763 one to verify a pair), and add the pair to our verified set; thus,
764 the number of verified-but-unused hashes stays constant until
765 we get to packet 13. At this point, packets still contain leaf data
766 (so we’ll consume one hash), but there are no more pairs left to
767 send; thus, our stockpile of hashes is steadily exhausted, until
768 we consume the final hash to verify the final packet.

769 This is a solid improvement! We dubbed it “Lockstep
770 Streaming,” after the fact that verification proceeds in lockstep
771 with packet receipt. But when we sat down to write the code
772 for matching verified-but-unused hashes to incoming leaves
773 and pairs, things got hairy. It was clearly *possible*, but the ug-
774 liness of the logic suggested that there was a better way. And
775 after filling plenty of notebook pages with hand-drawn Merkle
776 trees, `~rovnyx-ricfer` found it: a mapping of packet numbers
777 to hash pairs that was not only much cleaner, but also *scale
778 invariant*. It’s called Blackman ordering, and it looks like this:

779 See the difference? Instead of ordering the pairs on a first-
 780 needed basis, we jump around a bit. Specifically, we send a pair
 781 whose “height” corresponds to the number of trailing zeroes in
 782 the binary representation of the packet number. For example,
 783 packet 4 is 0b100 in binary, with two trailing zeroes, so we send
 784 pair d, which sits two levels above the leaves.⁴ Here is a packet-
 785 by-packet verification for Blackman ordering:

786 The $[x, y)$ notation indicates a half-open set, i. e. it includes
 787 $x, x+1, x+2, \dots, y-1$. $[2, 4)$ contains elements 2 and 3. $[0, 1)$ con-
 788 tains the single element 0.

```
789 Packet 0: Signed Merkle root + Merkle proof for leaf 0.
790     Verify proof against signed root.
791     We now have [0,1), [1,2), [2,4), [4,8), [8,16),
792     and [16,19].
793 Packet 1: Leaf 0 + Pair a.
794     Verify leaf 0 against [0,1).
795     Verify pair a against [2,4).
796     We now have [1,2), [2,3), [3,4), [4,8), [8,16),
797     and [16,19].
798 Packet 2: Leaf 1 + Pair b.
799     Verify leaf 1 against [1,2).
800     Verify pair b against [4,8).
801     We now have [2,3), [3,4), [4,6), [6,8), [8,16),
802     and [16,19].
803 Packet 3: Leaf 2 + Pair c.
804     Verify leaf 2 against [2,3).
805     Verify pair c against [4,6).
806     We now have [3,4), [4,5), [5,6), [6,8), [8,16),
807     and [16,19].
808 ... and so on.
```

⁴As you might expect, the logic gets slightly less clean when the number of leaves is not a power of two, but it's hardly catastrophic.

809 Shortly after, `~watter-parter` tweaked the ordering
810 slightly, offsetting it by one; this further simplified the low-
811 level bithacking. We called this variant “Lackman ordering,”
812 and it’s what we used in the final version of Lockstep Stream-
813 ing.

814 Packet-by-packet verification for Lackman ordering looks
815 like this:

```
816 Packet 0: Signed Merkle root + Merkle proof for leaf 0.  
817         Verify proof against signed root.  
818         We now have [0,1), [1,2), [2,4), [4,8), [8,16),  
819         and [16,19).  
820 Packet 1: Leaf 0 (no pair).  
821         Verify leaf 0 against [0,1).  
822         We now have [1,2), [2,4), [4,8), [8,16), and  
823         [16,19).  
824 Packet 2: Leaf 1 + Pair a.  
825         Verify leaf 1 against [1,2).  
826         Verify pair a against [2,4).  
827         We now have [2,3), [3,4), [4,8), [8,16), and  
828         [16,19).  
829 Packet 3: Leaf 2 + Pair b.  
830         Verify leaf 2 against [2,3).  
831         Verify pair b against [4,8).  
832         We now have [3,4), [4,6), [6,8), [8,16), and  
833         [16,19).  
834 ... and so on.
```

835 Compared to Blackman ordering, the pairs appear offset by
836 one position, which simplifies the bit-manipulation logic for
837 computing which pair to include in each packet.

838 There’s one more optimization worth mentioning: If the
839 message is small enough, we can skip the initial step of sending
840 a packet containing only a Merkle proof (with no leaf data).
841 Obviously, for a one-leaf message, we can simply send that leaf;
842 the hash of that leaf is the Merkle root. For a two-leaf message,
843 we can send the leaf plus its sibling hash ([1,2)); the verifier
844 can hash the first leaf and combine it with the sibling hash to
845 recover the root. And for a three- or four-leaf message, we can
846 send [1,2) and [2,3) (or [2,4), respectively). That’s the limit,
847 though; if a message has five leaves, we would need to send at

848 least three sibling hashes for the verifier to recompute the root,
849 but our packet framing only allows up to two hashes.

850 **4.2.1 Arena Allocator**

851 Directed Messaging uses a simple bump allocator arena for
852 memory management. Each arena is a contiguous block of
853 memory with three pointers: the start of the allocation (`dat`),
854 the current allocation position (`beg`), and the end of the block
855 (`end`). The `new()` macro allocates objects by advancing the `beg`
856 pointer with proper alignment.

857 The arena allocator provides *no individual deallocation* –
858 once memory is allocated from an arena, it can't be freed sepa-
859 rately. Instead, the entire arena is freed at once when the data
860 structure that owns it is destroyed.

861 **Allocation Patterns** Arenas are created with sizes tailored to
862 their use case:

- 863 • **Pending Interest Table entries** use 16 KiB arenas.
864 These store lane addresses for pending requests, with the
865 arena holding the entry itself plus a linked list of address
866 records.
- 867 • **Pending requests** allocate arenas at $5\times$ the expected
868 message size. A request receiving a 1 MiB message gets
869 a 5 MiB arena. This single arena holds the request state,
870 fragment data buffer, LSS authentication pairs, packet
871 statistics, bitset tracking received fragments, and pre-
872 serialized request packets.
- 873 • **Jumbo frame cache entries** allocate based on proof
874 size, data size, hash pairs, plus a 2 KiB buffer. For a 1 MiB
875 message, this might be around 1–2 MiB. The arena stores
876 the cached response data, Merkle proof spine, and au-
877 thentication hashes.
- 878 • **Temporary arenas** for packet sending use message size
879 plus 16 KiB to hold serialized packets plus overhead.

- 880 • **Scry callbacks** get small arenas for asynchronous Arvo
881 interactions.

882 **Deallocation Triggers** Arenas are freed only when their parent
883 data structure is destroyed:

- 884 • **Request completion:** When all fragments arrive, the
885 request is deleted and its arena freed. This happens asyn-
886 chronously through libuv's handle cleanup to ensure
887 proper timer shutdown before freeing memory.
- 888 • **Authentication failure:** If LSS verification fails while
889 processing fragments, the entire request is immediately
890 deleted.
- 891 • **Timeout expiration:** When retry timers exhaust their
892 attempts, the request is deleted.
- 893 • **PIT expiration:** After 20 seconds, entries are cleaned
894 from the Pending Interest Table.
- 895 • **Cache eviction:** When the jumbo cache exceeds
896 200 MiB, it's entirely cleared and all cached arenas are
897 freed.

898 **Lifecycle** A typical request lifecycle:

- 899 1. **Allocation:** Receive initial packet, create arena with 5×
900 data size, allocate all request state from arena.
- 901 2. **Growth:** As fragments arrive, write into pre-allocated
902 buffers within the arena.
- 903 3. **Completion:** All fragments received, construct final
904 message, send to Arvo.
- 905 4. **Cleanup:** Delete request from map, stop timer, close
906 handle asynchronously.
- 907 5. **Deallocation:** In UV callback, free entire arena with
908 single call.

909 This design trades memory efficiency for speed. Arenas
910 may hold unused space, but allocation is extremely fast (just
911 pointer arithmetic), and the single-free design eliminates per-
912 object deallocation overhead and fragmentation issues.

913 4.2.2 Download Checkpointing

914 This has not been deployed to the network, but this design al-
915 lows the requesting ship’s runtime to inject jumbo frames of
916 arbitrary size into its Arvo as each one finishes downloading,
917 with real authentication by using Lockstep. Arvo will seam-
918 lessly store those jumbo frames and accumulate them until it
919 has the whole message, at which time it will deserialize the
920 message into an Urbit ‘noun’ data structure and deliver it to the
921 application or kernel module that had triggered the request.

922 This allows the system to make effective use of Arvo as a
923 download checkpointing system. After a process crash, ma-
924 chine restart, or any other transient failure, the download can
925 be resumed with minimal loss of information.

926 Injecting an authenticated jumbo frame into Arvo main-
927 tains a security boundary. Urbit’s main runtime, Vere, has two
928 Unix processes: one runs the Arvo kernel, and the other han-
929 dles input and output. Arvo maintains ultimate responsibility
930 for cryptographic operations. This lets the private key remain
931 solely in the Arvo process, leaving the I/O process without the
932 ability to encrypt, decrypt, authenticate, or verify authentica-
933 tion.

934 Instead, the runtime delegates any operation requiring a
935 private key to Arvo, including validating the message-level au-
936 thentication in the first packet of a scry response. To add a
937 layer of defense in depth in case the I/O process is compro-
938 mised, Arvo performs its own packet validation, including the
939 Lockstep packet authentication. This remains efficient because
940 each packet can be a large jumbo frame.

941 Checkpointing has another benefit. No matter how large a
942 message is, the downloader can keep a fixed upper bound on
943 the memory footprint while download that message, propor-
944 tional to one jumbo frame.

945 4.2.3 Download Resumption

946 After a transient failure – most commonly a process crash or
947 machine restart – a requesting ship can resume a download.
948 In order to pick up from where it left off, the runtime first
949 asks its local Arvo for the leaf-packet hashes it needs, which
950 Arvo generates on demand from the jumbo frames that have al-
951 ready been downloaded and stored in Arvo. This is $O(\log(n))$
952 hashes, where n is the message length, and no message data
953 needs to be sent over inter-process communication in order to
954 resume a download, preventing restarts from becoming slow
955 and memory-intensive.

956 Once the runtime has the hashes it needs, it resumes the
957 Lockstep streaming verification that it had been doing, begin-
958 ning with the next jumbo frame after the last one that had been
959 downloaded and saved in Arvo.

960 Download checkpointing and resumption together provide
961 a good set of tools for download management. This is beyond
962 what TCP provides, or even HTTP. HTTP has resumption head-
963 ers, but both client and server have to opt into using them, so
964 in practice many HTTP-based downloads cannot be resumed.

965 5 Congestion Control

966 In Directed Messaging, congestion control is pluggable. The re-
967 questing ship decides how many request packets to send and at
968 what time. The publisher ship is only responsible for respond-
969 ing to requests and does not participate in congestion control.

970 It is possible for an Urbit implementation to have function-
971 ing, if not performant, networking, without any runtime im-
972 plementation of congestion control. The formal specification
973 in the networking module of the Arvo kernel for how a ship
974 sends request packets is a simple one-at-a-time indefinite re-
975 peating timer. The ship sends the first request packet, repeat-
976 ing it every thirty seconds until a response packet is heard, at
977 which point it begins requesting the next packet.

978 Performant congestion control, then, is an extension of Ur-
979 bit's idea of a “jet”, i. e. a peephole optimization that replaces

980 a built-in function, defined formally but is likely slow, with an
981 optimized low-level implementation.

982 In practice, this slow packet re-send is used for retrying
983 dead connections, where the publishing ship has been unre-
984 sponsive for a long time. This is important because Urbit net-
985 work requests generally do not time out at the application
986 level; they are considered persistent, and they must be retried
987 indefinitely. Fast, runtime-based congestion control only kicks
988 in when the runtime receives a response packet, indicating the
989 publishing ship has become responsive.

990 The current implementation of Directed Messaging em-
991 ploys a modified TCP Tahoe-style congestion control algo-
992 rithm adapted to its request/response architecture and packet-
993 oriented nature. The protocol's congestion control differs from
994 traditional TCP in several fundamental ways due to its pull-
995 based communication model and implicit acknowledgment
996 scheme.

997 5.1 Architectural Foundation

998 Unlike TCP's push-based model where senders transmit data
999 and await separate acknowledgment packets, Directed Mes-
1000 saging operates on a request/response paradigm. The request-
1001 ing ship sends PEEK packets to solicit specific fragments, and
1002 the responding ship sends PAGE packets containing the re-
1003 quested data. The arrival of each PAGE packet serves as an im-
1004 plicit acknowledgment – no separate ACK packets exist in the
1005 protocol. This inversion places congestion control responsibil-
1006 ity on the requester rather than the sender, allowing the party
1007 pulling data to directly regulate network load.

1008 The protocol operates on fixed-size fragments rather than
1009 byte streams. Each fragment contains up to 1024 bytes of pay-
1010 load data (at the default \$blob parameter of 13). The con-
1011 gestion window (cwnd) measures capacity in fragment count
1012 rather than bytes, providing coarser but simpler granularity
1013 than TCP's byte-oriented approach.

1014 5.2 State Variables

1015 Congestion control state is maintained per peer and includes:

- 1016 • **cwnd** (congestion window): Number of fragments al-
1017 lowed in flight simultaneously.
- 1018 • **ssthresh** (slow start threshold): Boundary between ex-
1019 ponential and linear growth phases.
- 1020 • **rttvar** (RTT variance): Smoothed variance in round-trip
1021 measurements.
- 1022 • **rto** (retransmission timeout): Calculated timeout for loss
1023 detection.

1024 Per-request state tracks which fragments have been sent, when
1025 they were sent, how many retransmission attempts have oc-
1026 curred, and which fragments have been received using an effi-
1027 cient bitset representation.

1028 5.3 Slow Start and Congestion Avoidance

1029 The protocol implements two growth phases analogous to TCP:

- 1030 • **Slow Start Phase** ($cwnd < ssthresh$): Upon initiating a
1031 request or recovering from congestion, $cwnd$ begins at
1032 one fragment. For each fragment acknowledgment re-
1033 ceived (implicitly, by receiving the corresponding PAGE
1034 packet), $cwnd$ increments by 1. This produces expo-
1035 nential growth: $1 \rightarrow 2 \rightarrow 4 \rightarrow 8 \rightarrow 16$, allowing rapid probing
1036 of available bandwidth.
- 1037 • **Congestion Avoidance Phase** ($cwnd \geq ssthresh$): Once
1038 $cwnd$ reaches $ssthresh$, growth becomes linear.
1039 The implementation uses a fractional accumulation
1040 strategy: for each acknowledgment, a fractional counter
1041 accumulates $1/cwnd$ of a window increment. When
1042 the accumulated value reaches $cwnd$, the actual $cwnd$
1043 increments by 1, yielding approximately one window
1044 size increase per round-trip time.

1045 The default `ssthresh` is initialized to 10,000 fragments (approximately
1046 10 MiB), effectively allowing slow start to dominate for
1047 typical transfer sizes.

1048 **5.4 Loss Detection and Recovery**

1049 Directed Messaging currently implements timeout-based loss
1050 detection only, without fast retransmit or fast recovery mech-
1051 anisms. This places it closest to TCP Tahoe's behavior, though
1052 with an important modification to timeout handling.

- 1053 • **Timeout Detection:** Each in-flight fragment's trans-
1054 mission time is recorded. A retransmission timer fires
1055 when the oldest unacknowledged fragment exceeds the
1056 calculated RTO. The protocol scans all in-flight fragments
1057 upon timeout and retransmits any that have been out-
1058 standing beyond the RTO interval.
- 1059 • **Timeout Response:** Upon detecting packet loss via
1060 timeout, the protocol reduces network load by:
 - 1061 1. Setting `ssthresh` = $\max(1, \text{cwnd} / 2)$.
 - 1062 2. Setting `cwnd` = `ssthresh`.
 - 1063 3. Doubling `rto` (up to a maximum bound).

1064 This differs from TCP Tahoe, which sets `cwnd` = 1 and restarts
1065 slow start from the beginning. Directed Messaging's approach
1066 is less conservative, immediately resuming transmission at the
1067 reduced threshold rather than slowly ramping up from a single
1068 packet. This assumes that while congestion occurred, the net-
1069 work can still sustain traffic at half the previous rate without
1070 requiring a full slow start restart.

1071 The lack of fast retransmit (triggering on three duplicate ac-
1072 knowledgments) represents a significant difference from mod-
1073 ern TCP variants. Fast retransmit requires detecting duplicate
1074 acks, which in Directed Messaging would mean detecting re-
1075 quests for the same fragment. However, the current implemen-
1076 tation treats each arriving PAGE packet independently without
1077 tracking the ordering implications that would enable fast re-
1078 transmit. This is a known simplification intended for future
1079 enhancement.

1080 5.5 Round-Trip Time Estimation

1081 The protocol employs Jacobson/Karels RTT estimation, the
1082 same algorithm used in TCP. When a fragment acknowledg-
1083 ment arrives (excluding retransmissions), the round-trip time
1084 measurement (`rtt_datum`) is calculated as the difference be-
1085 tween current time and transmission time.

1086 RTT smoothing uses exponential weighted moving aver-
1087 ages with traditional TCP parameters:

- 1088 • $\text{rtt} = (\text{rtt_datum} + 7 \cdot \text{rtt}) / 8$, $\alpha = 1/8$.
- 1089 • $\text{rttvar} = (|\text{rtt_datum} - \text{rtt}| + 7 \cdot \text{rttvar}) / 8$, $\beta = 1/4$.
- 1090 • $\text{rto} = \text{rtt} + 4 \cdot \text{rttvar}$.

1091 The retransmission timeout `rto` is furthermore clamped to a
1092 minimum of 200 milliseconds and a maximum that varies by
1093 context (typically 2 minutes for most traffic, 25 seconds for
1094 keepalive probes to sponsors).

1095 Retransmitted fragments do not contribute to RTT esti-
1096 mation, following Karn's algorithm to avoid ambiguity about
1097 which transmission is being acknowledged.

1098 5.6 Selective Request Architecture

1099 The implicit acknowledgment scheme combines naturally with
1100 selective fragment requesting. The protocol maintains a bitset
1101 tracking which fragments have been received. When request-
1102 ing additional fragments during congestion-controlled trans-
1103 mission, the requester consults both the congestion window
1104 (how many new requests can be sent) and the bitset (which
1105 fragments are needed). This provides the benefits of TCP SACK
1106 without requiring additional protocol machinery – selectivity
1107 is inherent to the request/response model.

1108 When fragments arrive out of order, the LSS (Lockstep Sig-
1109 nature Scheme) authentication requires buffering misordered
1110 packets until their Merkle proof predecessors arrive. Once au-
1111 thenticated, these fragments are marked received in the bitset,
1112 and the congestion control state updates accordingly.

1113 **5.7 Request Rate Limiting**

1114 The congestion window limits the number of PEEK requests
1115 in flight. Before sending additional requests, the protocol
1116 calculates

1117 `available_window = cwnd - outstanding_requests`

1118 where `outstanding_requests` counts fragments that have been
1119 requested but not yet received. This naturally throttles the request rate according to observed network capacity.
1120 As PAGE packets arrive (serving as acknowledgments),
1121 `outstanding_requests` decreases, allowing new PEEK packets to
1122 be sent.

1124 This pull-based flow control provides inherent advantages:
1125 the requester cannot be overwhelmed by data it didn't request,
1126 and the congestion control directly limits the rate at which the
1127 requester pulls data from the network.

1128 **5.8 Per-Peer State Management**

1129 Congestion control state is maintained per peer rather than per
1130 connection or per flow. All concurrent requests to the same
1131 peer share a single congestion window and RTT estimate. This
1132 design choice reflects the architectural principle that network
1133 capacity constraints exist between pairs of ships rather than
1134 between individual conversations.

1135 Sharing state across requests to the same peer provides several benefits:

- 1137 1. RTT measurements from any request improve estimates
1138 for all requests.
- 1139 2. Congestion signals from one request protect other concurrent requests.
- 1141 3. State initialization costs are amortized across multiple requests.
- 1143 4. The aggregate transmission rate to each peer is controlled.

1145 However, this also means that multiple concurrent large trans-
1146 fers to the same peer must share available bandwidth, which
1147 could reduce throughput compared to per-flow windows in
1148 some scenarios.

1149 5.9 Initial Window and Probing

1150 New peer connections begin with conservative initial values:
1151 `cwnd = 1, rtt = 1000 ms, rttvar = 1000 ms, rto = 200 ms`. The
1152 first fragment request initiates RTT measurement and slow
1153 start growth. This cautious initialization ensures the protocol
1154 probes network capacity gradually rather than assuming high
1155 bandwidth is available.

1156 For peers with no recent traffic, the congestion state per-
1157 sists but becomes stale. Future enhancements may include
1158 state expiration and re-initialization after prolonged idle pe-
1159 riods, though the current implementation maintains state in-
1160 definitely once a peer is known.

1161 5.10 Comparison with TCP Variants

1162 The congestion control algorithm most closely resembles TCP
1163 Tahoe but with notable differences:

1164 Similarities to Tahoe:

- 1165 • Slow start with exponential growth
- 1166 • Congestion avoidance with linear growth
- 1167 • Loss detection via timeout only
- 1168 • Conservative initial probing

1169 Differences from Tahoe:

- 1170 • Modified timeout recovery (`cwnd = ssthresh` rather than
1171 `cwnd = 1`)
- 1172 • Packet-oriented rather than byte-oriented windows
- 1173 • Implicit acknowledgment via data receipt

- 1174 • Pull-based rather than push-based architecture

- 1175 • Per-peer rather than per-connection state

1176 Compared to NewReno/SACK, the protocol lacks fast re-
1177 transmit and fast recovery, making it less responsive to iso-
1178 lated packet loss. However, the selective request architecture
1179 provides the functional benefits of SACK naturally. The implicit
1180 acknowledgment scheme eliminates issues with ACK loss and
1181 compression that affect TCP.

1182 5.11 Design Trade-offs

1183 The congestion control design reflects several architectural
1184 trade-offs. Advantages include:

- 1185 • Simpler than modern TCP variants (no fast recovery com-
1186 plexity).
- 1187 • Natural selective acknowledgment through request/re-
1188 sponse model.
- 1189 • Requester controls rate, preventing receiver overwhelm.
- 1190 • No separate ACK channel to fail.
- 1191 • Precise retransmission control with bitset tracking.

1192 The limitations include:

- 1193 • Lack of fast retransmit increases latency for isolated
1194 losses.
- 1195 • Packet-oriented windows provide coarser bandwidth
1196 control.
- 1197 • Per-peer state sharing may reduce throughput for con-
1198 current flows.
- 1199 • Modified timeout behavior is less studied than standard
1200 algorithms.

1201 5.12 Future Enhancements

1202 The protocol architecture supports several potential improve-
1203 ments without fundamental redesign. Fast retransmit could be
1204 implemented by tracking fragment request patterns and de-
1205 tecting when requests skip over missing fragments. Fast re-
1206 covery could leverage the existing `ssthresh` calculation while
1207 avoiding the full slow start restart. Additional sophistication
1208 in RTT measurement could distinguish network delay from ap-
1209 plication processing time.

1210 The current implementation represents a pragmatic bal-
1211 ance between simplicity and effectiveness, providing reason-
1212 able congestion control while keeping the protocol accessible
1213 to implementation and formal verification.

1214 6 Integration

1215 In order to deploy Directed Messaing to Urbit's live network,
1216 the previous version of the protocol needed to remain opera-
1217 tional, since there is no central authority that can force Urbit
1218 ships to update to a particular version. The authors decided
1219 further that each ship should be able to upgrade connections
1220 to peer ships one by one and be able to downgrade it without
1221 data loss.

1222 This was possible due to the persistent, transactional nature
1223 of both the previous and new versions of the protocol.

1224 6.1 Ames Flows

1225 The Arvo kernel has a concept of an Ames "flow", a directed
1226 connection between ships where the subscriber ship can send
1227 commands and the publisher ship can send responses, both as
1228 "commands" at the level of Directed Messaging.

1229 The implementation of Directed Messaging maintained the
1230 interface to the rest of the system, without modification. Ap-
1231 plications do not need to modify their code at all to make use
1232 of Directed Messaging.

1233 7 Conclusion

1234 Directed Messaging provides a secure, efficient, and robust
1235 mechanism for requesting and receiving large messages in the
1236 Urbit network. By leveraging Lockstep Streaming for packet
1237 authentication and a modified TCP-like congestion control al-
1238 gorithm, it achieves high throughput while maintaining data
1239 integrity and resilience to network conditions. The protocol's
1240 design reflects Urbit's architectural principles of pull-based
1241 communication, implicit acknowledgment, and per-peer state
1242 management. Directed Messaging represents a significant ad-
1243 vancement over previous messaging protocols in Urbit, en-
1244 abling applications to reliably transfer large amounts of data
1245 across the decentralized network.✉

1246 8 Future Work

1247 TODO not sure what to include here @TED why don't we drop
1248 this section and work anything else into the main body and
1249 anything speculative into a conclusion?

- 1250 • star relaying
- 1251 • star scry caching
- 1252 • download checkpointing and resumption
- 1253 • add fast retransmit to congestion control

1254 speculative: - add %pine - add sticky scry Those together
1255 would flesh out a full pub-sub system with stateless publishers
