4 Abstract

5 Urbit's networking protocol was redesigned
6 achieving over 100× throughput improvements while
7 implementing content-centric networking in a produc-
8 tion peer-to-peer system. Unlike address-based routing,
9 all network operations (queries and commands) are ex-
10 pressed as remote namespace reads. Urbit's immutable
11 scry namespace enables efficient caching, determin-
12 istic encryption, and stateless publishing, while a
13 pre-distributed PKI eliminates handshake overhead for
14 single-roundtrip transactions. Lockstep Streaming, a
15 novel scale-invariant packet authentication scheme
16 using binary numeral trees, maintains authentication
17 integrity across variable MTU sizes at relay hops. The
18 Lackman traversal pattern enables constant-space
19 streaming authentication. Directed routing simplifies
20 peer discovery and NAT traversal compared to previous
21 approaches, while source-independent routing mini-
22 mizes relay state. Begun in 2023 under the auspices
23 of the Urbit Foundation and deployed in early 2025,
24 Directed Messaging represents the first large-scale
25 deployment of content-centric networking.

66 1 Introduction

67 The Directed Messaging project was a fundamental overhaul
68 of Urbit’s networking stack. It rewrote the protocol definition
69 and the protocol implementation, split between Hoon code
70 inside Arvo (the Urbit overlay OS), and C code in Vere (the
71 Urbit runtime). Directed Messaging addressed several major
72 limitations of Urbit’s previous networking stack: it increased
73 throughput by over $100\times$, improved peer discovery reliability,
74 enabled the scalability of content delivery, and introduced
75 a modular internal architecture that reduced implementation
76 complexity. Directed Messaging is an encrypted, authenticated,
77 peer-to-peer, packet-switched, message-oriented, connectionless,
78 content-centric, transactional network protocol with its
79 own congestion control, transmission control, and packet-level
80 authentication. It was deployed to the Urbit network in early
81 2025.

82 These improvements were driven by Directed Messaging’s total adherence to a request-response discipline throughout
83 the stack, bundled with heavy use of Urbit’s immutable
84 referentially-transparent global namespace, called the “scry
85 namespace”. Every network message is either a request for
86 data at a “scry path” (Urbit’s equivalent of a URL), or an authenticated
87 response that includes the data at that path. This is true at the message layer and the packet layer, and for both
88 reads (queries) and writes (commands).

89 Before Directed Messaging, the bandwidth Urbit was able
90 to utilize was extremely limited, maxing out in the hundreds of

93 kilobytes per second. It lacked orders of magnitude of performance
94 in order to make effective use of commodity networking hardware,
95 such as on a laptop or cloud instance. With Directed Messaging,
96 Urbit’s networking speed was able to reach over 1 gigabit/s on commodity hardware, sufficient for the vast majority of contemporary personal use cases.

97
98
99 Directed Messaging managed to improve throughput while
100 preserving Urbit’s already-good latency performance. For
101 small messages, a network transaction is accomplished in one
102 roundtrip: a command sent one way, followed by an acknowledgement
103 the other way. Due to Urbit’s public key infrastructure (PKI)
104 being disseminated to all nodes *a priori* from a Byzantine fault-tolerant source (the Ethereum blockchain and
105 a bespoke L2 for economic efficiency), no cryptographic handshake
106 is needed for two Urbit nodes (called “ship”s in Urbit
107 lingo) to begin communication – even their first exchange is a
108 single roundtrip.
109

110 In addition to performance improvements, Directed Messaging scales better by leveraging runtime caching to disseminate
111 data to many clients simultaneously. This strategy is particularly effective within Urbit’s immutable scry namespace.
112 Directed Messaging also introduces a new procedure for peer discovery and routing that is much more reliable and performant
113 than the previous setups. It deals better with NAT traversal and with using supernodes as relays more efficiently and
114 reliably.
115

116 All of this is done by simplifying the basic networking structure to enforce a rigid request-response discipline
117 throughout the entire system. In addition to that, it also places all network messages, including acknowledgments and commands,
118 in addition to responses for queries asking for data, into Urbit’s immutable namespace, called the scry namespace. This makes Urbit’s entire networking stack a named data networking system, which is also called content-centric networking.
119 As far as the authors know, Directed Messaging is the very first production deployment of a content-centric networking
120 protocol, as well as the deployment with the largest number of nodes. Not only that, its content-centricity preserves the
121 immutability of Urbit’s namespace throughout the stack. The

128
129
130
131

132 immutability is key to the scalability improvements and reli-
133 ability improvements, and it also helps with single-threaded
134 performance.

135 Along the way, we designed and implemented a novel
136 scheme for streaming packet authentication. This helps pre-
137 vent denial-of-service attacks that could forge individual pack-
138 ets and spoof them in order to invalidate a large download.
139 This attack is prevented by authenticating every packet, but
140 unlike the previous version of Urbit’s networking stack, which
141 authenticated each packet with a signature (meaning one sig-
142 nature for every kilobyte of data, which was extremely ineffi-
143 cient), there’s only one signature per message. A Merkleiza-
144 tion scheme using binary numeral trees (TODO: cite) is used
145 to authenticate the packets within that message.

146 This achieves a property that, to our knowledge, has not
147 been demonstrated in prior packet authentication schemes:
148 the ability to handle a different maximum transmission unit
149 (MTU) at each hop in a relay chain without losing packet-level
150 authentication. It is a scale-invariant packet-authentication
151 scheme, and it also has good memory use characteristics, due
152 to a novel algorithm based on the “Lackman” scale-invariant
153 tree-traversal pattern developed by the authors. A relay re-
154 ceiving packets of one size and emitting packets of another size
155 only needs to hold one large packet in memory while stream-
156 ing (e.g. if receiving 1 kiB packets and sending 16kiB pack-
157 ets, it only needs to store 16 kiB of packet data at a time). It
158 can seamlessly handle any MTU that is one kilobyte, two kilo-
159 bytes, or any power-of-two number of kilobytes above that, up
160 to 128 MiB.

161 Another advantage of the Directed Messaging protocol is
162 that much more of the logic can be offloaded from the Urbit
163 operating system, Arvo, into the runtime. This enables de-
164 coupling between the formal specification, which is written in
165 Nock, and implementation, which is written in C. This is in
166 keeping with the spirit of Urbit’s “jet” system that separates
167 mechanism and policy for code execution. The most straight-
168 forward advantage of this decoupling is that each packet can
169 be processed ephemerally, without incurring a disk write as in
170 previous versions of Urbit’s network protocol – that was a se-

171 vere bottleneck on the maximum throughput. The implemen-
172 tation in the runtime could be swapped out with another im-
173 plementation written in another language, the congestion con-
174 trol algorithm could be swapped out, and parallelism strategies
175 could readily be employed to increase multicore CPU utiliza-
176 tion. The implementation that was deployed contains a major
177 optimization: specialized arena allocators to reduce memory
178 management overhead.

179 2 High-Level Protocol Design

180 2.1 Request/Response, Namespace Reads

181 The protocol design is based off the idea of a remote names-
182 pace read, wherein a “subscriber” ship requests data from a
183 “publisher” ship, and the publisher sends that data as the re-
184 sponse. The publisher ship makes the data available over the
185 network by assigning it a path in Urbit’s “scry” namespace and
186 setting permissions appropriately (permissioning will be de-
187 scribed fully in a later section). The subscriber ship, then, can
188 download data from another ship by sending it a request for
189 the data at a path and waiting for the response.

190 A network roundtrip is conceived of as a request, followed
191 by a response. The request consists of a “scry request”, i. e.
192 a request for data at a “scry path”. An example scry path is
193 `/~zod/1/2/c/x/~2025.9.22/sys/kelvin`. A scry path immutably
194 names a datum, in this case the `sys.kelvin` file published by
195 `~zod` (at `rift=1` and `life=2`), within the `%c` kernel module
196 (Clay, the revision control system), with request type `%x` (re-
197 quest file contents), and with timestamp at the start of the day
198 on September 22, 2025. When a ship receives a scry request
199 over the network, it can respond by sending a “scry response”
200 containing the datum bound to that path.

201 Over the network, a network request is a single UDP packet
202 that encodes a scry path, limited to 384 characters so the re-
203 quest packet always fits into the internet-standard 1500-byte
204 MTU (maximum transmission unit). A scry response may con-
205 sist of a single packet, or multiple packets, depending on the

206 size of the datum bound to that path. If the datum is 1kiB or
207 less, the response is encoded into a single UDP packet. Otherwise,
208 the first scry response packet contains only the first
209 1kiB of the datum, along with a fixed-width field containing
210 the number of bits in the whole datum.

211 If the subscriber ship receives a response indicating the da-
212 tum is multi-packet, it switches modes and begins requesting
213 the remainder of the datum, one kiB at a time. Each request for
214 a kiB of data is itself a fully-fledged namespace read request,
215 where the path in the request contains the path of the whole
216 datum as well as the chunk size being requested (configured to
217 1 kiB over the public internet, but this could be increased to any
218 power of 2 kiB's up to 128 MiB, for other environments, such
219 as intra-datacenter). The protocol definition does not require
220 those fragment requests to be sent in any particular order or
221 according to any particular congestion control algorithm. The
222 current implementation uses a packet-switched variant of the
223 TCP NewReno congestion control algorithm, written in C in
224 Urbit's runtime, to manage multi-packet reads. The message-
225 level authentication is sent in the first response packet. Each
226 subsequent packet is authenticated as being part of that mes-
227 sage by using the LockStep streaming authentication scheme,
228 described in a later section.

229 This remote read flow is a “pure read”: handling a read re-
230 quest does not require the publisher ship to change any persis-
231 tent state. But a general-purpose network protocol needs to be
232 able to express commands, not just reads. Directed Messaging
233 builds commands out of reads. A command is conceived of as
234 two reads, one in each direction:

- 235 1. The ship sending the command makes the command da-
236 tum available within its own scry namespace, so the re-
237 ceiving ship has the ability to read the command by send-
238 ing a remote read request.
- 239 2. The ship that receives the command, after attempting
240 to execute the command, makes the command's result
241 available within its namespace, so the sending ship has
242 the ability to read the result (hereafter called the “ack”)

243 by sending a remote read request. A result can be suc-
244 cess (“ack”) or an error datum (“naxplanation”, named
245 after “nack” for negative acknowledgment).

246 This approach is conceptually clean but immediately
247 presents two practical challenges. The first is triggering: how
248 does the receiving ship *know* to request the command datum
249 from the sending ship? There are many ships on the network;
250 it would be absurdly impractical to send requests to all of them
251 on the off-chance that one or two of them have an outstanding
252 command for us. The second challenge is latency: a naive im-
253 plementation would imply every command requires two net-
254 work roundtrips, one to remote-read the command and one
255 to remote-read the command’s result (ack or naxplanation).
256 If so, that would be unfortunate, since Urbit’s previous net-
257 working required only one roundtrip for a command and ack,
258 in the common case of a small (≤ 1 kiB) command datum, and
259 unneeded roundtrips are anathema to a good user experience
260 (Cheshire, 1996).

261 Fortunately, we can solve both problems with one weird
262 trick. We add a ‘request-type’ bit to each network request
263 packet indicating whether it is a read or a command, and if
264 it is a command, it includes not only the scry request path, but
265 also a scry response containing the first 1 kiB of the command
266 datum. When the receiving ship’s runtime receives the packet,
267 it looks at the ‘request-type’ bit to determine how to handle the
268 packet.

269 If the incoming request packet is a read, the runtime per-
270 forms a read request on the Arvo OS by firing its `+peek` arm,
271 a Nock function that reads from Arvo’s namespace. This read
272 request does not trigger any disk writes and could be run in
273 parallel with other reads and with an Arvo event. The runtime
274 then encodes the result of this read as a scry response packet
275 and sends it back to the IP and port that sent the request.

276 If the packet is a command, the runtime injects the packet
277 as a stateful Arvo “event” by firing its `+poke` arm (a Nock func-
278 tion that sends an event or command for Arvo to process, pro-
279 ducing effects and a new Arvo OS with a modified state). When
280 this event completes, one of the effects it produces can be a

281 scry response packet containing the ack, which the runtime
282 will send back to the IP and port that sent the request.

283 If the command datum fits within 1 kiB, the entire com-
284 mand is sent in the first packet, recapturing the single-
285 roundtrip flow for a command and an ack. Multi-packet com-
286 mands are downloaded by the commanded ship using the same
287 congestion control as downloading any other potentially large
288 datum – and, importantly, those incremental downloads do not
289 necessarily trigger unnecessarily frequent disk writes.

290

3 Routing

291

3.1 Directed Routing

292 The Directed Messaging protocol gets its name from its rout-
293 ing scheme, which treats each bidirectional communication be-
294 tween two Urbit ships as directed, like a directed edge in a
295 graph. For each request/response roundtrip, one ship is the
296 requester, and the other is the responder, and that distinction
297 is known at every layer of the system. Making this direction-
298 ality known to routing enables a routing paradigm where a re-
299 sponse packet traces the exact same relay path through the net-
300 work as the request path, in the reverse order. Previous Urbit
301 networking protocols used the opposite paradigm: “criss-cross
302 routing”, so-called because both request and response could be
303 routed through the destination ship’s “sponsor”, i. e. the su-
304 pernode ship (“galaxy” root node or “star” infrastructure node)
305 responsible for relaying packets to that ship. In contrast, in di-
306 rected routing, the request and the response both use the same
307 relay: the responder ship’s sponsor.

308

3.1.1 Request (Same for both Directed and Criss-Cross Routing)

309 requester's sponsor ----- responder's sponsor
310 / \
311 requester -----> responder

312 3.1.2 Response (Directed Routing)

```
313 requester's sponsor ----- responder's sponsor  
314           /           \\\n315 requester <----- ----- responder
```

316 3.1.3 Response (Criss-Cross Routing)

```
317 requester's sponsor ----- responder's sponsor  
318           /           \\\n319 requester <--- ----- responder
```

320 3.2 Relaying

321 Making the directedness of communication legible to relays
322 and Urbit runtimes allows the protocol to be a faithful, if Urbit-
323 specific, Named Data Networking (NDN) protocol, which had
324 been Urbit’s stated goal since 2010. A Directed Messaging re-
325 quest packet acts as an NDN “interest” packet, and a response
326 packet acts as an NDN “data” packet.

327 The NDN family of protocols, created by Van Jacobson et al.
328 in the mid-2000s, differs from traditional networking protocols
329 in that an interest packet has no sender address field – the iden-
330 tity of the sender of a request is unknown to the network. In-
331 stead, a receiver (relay or server) remembers “where” it heard
332 the request from, and sends the response back to that. The no-
333 tion of “where” varies depending on the layer of the stack the
334 system is operating at: for an IP replacement, a relay would
335 remember the physical interface (e.g. Ethernet port) on which
336 it heard the incoming request. When building on top of IP and
337 UDP, as Directed Messaging does, a receiver remembers the IP
338 and port of the sender.

339 Previous Urbit network protocols still included the sender’s
340 Urbit identity in the request packets, failing to achieve the
341 “source independence” property that defines NDN. Directed
342 Messaging is completely source-independent for reads, and for
343 commands, it piggybacks a source-independent response onto
344 a source-independent request in such a way that the receiver

345 does know which Urbit address sent the request, but not in a
346 way that requires packet routing to know or use the source
347 Urbit address.

348 Source independence lets the routing operate fully locally,
349 i. e. without reference to or knowledge of anything beyond a
350 single hop away in either direction. This minimizes the data
351 storage and synchronization requirements for nodes, which
352 could become significant at scale.

353 Source independence entails stateful routing. Directed
354 Messaging adopts NDN’s Pending Interest Table, which stores a
355 mapping from each outstanding request to the IP and port that
356 sent that request. If the request times out (after roughly 30 sec-
357 onds), or the request is satisfied by a response, the request is
358 deleted from the table.

359 Since responses are authenticated down to the packet level,
360 and immutable (meaning no cache invalidation is ever needed,
361 only eviction), it should be straightforward for relays to cache
362 responses, enabling efficient content distribution through the
363 network. At present, each Urbit ship’s runtime has a cache for
364 its own responses, but supernodes (galaxies and stars) do not
365 yet cache responses from their sponsored ships.

366 3.3 Peer Discovery

367 Urbit is a peer-to-peer network. Only root nodes (galaxies) list
368 their own IP addresses publicly (on the Ethereum blockchain);
369 all other ships must be discovered on demand. When one ship
370 first sends a request to another ship, it generally doesn’t know
371 at what IP and port that ship could be reached, and it also
372 doesn’t know if the ship is reachable directly, or behind a fire-
373 wall and only reachable through its sponsor.

374 The criss-cross routing used in previous Urbit protocols
375 was hard to work with in practice and suffered from ineffi-
376 ciencies and bugs. Directed Messaging has a simpler approach
377 to peer discovery that is easier to reason about.

378 The main difficulties with criss-cross routing stem from the
379 structure of the internet. Most residential internet connections
380 live behind a firewall that blocks all unsolicited incoming UDP
381 packets. A laptop at home can send an outgoing packet to

382 some destination IP and port, and the router will relay response
383 packets back to the laptop for some time afterward, usually
384 30 seconds, as long as those response packets come from that
385 same destination IP and port.

386 A UDP-based peer-to-peer network, then, needs to include
387 not only residential nodes but also nodes on the public inter-
388 net, not behind firewalls. These nodes must be discoverable
389 so that residential nodes can ping them every 25 seconds, to
390 ensure the residential nodes can receive messages. In Urbit,
391 these public nodes are the galaxies (root nodes) and stars (in-
392 frastructure nodes). For now, only galaxies perform routing,
393 due to edge cases with two levels of supernodes in peer discov-
394 ery using criss-cross routing – we expect Directed Messaging
395 will unblock stars from participating in routing.

396 When communicating with another ship for the first time,
397 a ship first sends the packet to the other ship's sponsoring
398 galaxy, which has an open connection to its sponsored ship
399 if it's online. The galaxy receives a ping every 25 seconds from
400 its sponsored ship. Whenever the source IP and port change,
401 the galaxy's runtime injects an Arvo event and its Arvo OS
402 saves the sponsored ship's new location to disk.

403 In Directed Messaging, when the galaxy receives a packet
404 intended for one of its sponsored ships, it relays the packet.
405 This uses the pending interest table described above to track
406 the fact that there is an outstanding request that the galaxy
407 is expecting to be honored by a response from the sponsored
408 ship. The fundamental invariant of directed routing is that the
409 response packet must trace the exact same path through the
410 network as the request packet had, just reversed. Since this
411 request had gone through this galaxy, the response must also
412 route through the galaxy.

413 In Urbit's previous protocols, in contrast, the response
414 would go directly from the sponsored ship back to the request-
415 ing ship, and also potentially through the requesting ship's
416 sponsoring galaxy. This works in principle, but one drawback
417 has to do with "route tightening" (described below): the re-
418 sponse route only tightens to a direct route (without relays) if
419 there are requests flowing in both directions; otherwise every
420 response will flow through the requester's sponsor, even if the

421 requester is not behind a firewall.

422 3.4 Route Tightening

423 It is better for performance, scaling, and individual sovereignty
424 to obtain a direct route to another ship, rather than communicating
425 through relays. In order to facilitate this, the system
426 must automatically “tighten” a route over time to reduce the
427 number of hops. Directed Messaging accomplishes this in the
428 relay. When a relay receives a response packet (originally sent
429 by a transitively sponsored ship, but possibly through a relay
430 once stars begin relaying packets), it appends the IP and port
431 from which it heard that packet to the end of the packet before
432 forwarding it to the requesting ship. Once the requesting
433 ship receives this augmented packet, it knows the address appended
434 to that packet is next hop in the relay chain. Once it knows that,
435 when it sends packets to the responding ship, it can send them through
436 the first hop in the relay chain (the receiving ship’s galaxy), or to the next hop, which could be another
437 relay or the ship itself.

438 In the current implementation, the requesting ship uses a simple procedure to decide which routes to send the packet on. It tracks the date of the last received packet from both the direct route and the route through the galaxy. A route is considered active if a packet has been received on it within the last five seconds. When the requesting ship goes to send a packet, if the direct route is active, it sends the packet on that route. Otherwise, it sends the packet through the galaxy and also sends a copy of the packet on the direct route as a probe.

439 This ensures continuity of communication when switching to or from a direct route, and it automatically tightens to the direct route if the direct route is responsive and loosens to the galaxy route if the direct route becomes unresponsive.

452 4 Authentication and Encryption

453 Directed Messaging is always authenticated and supports encryption in a number of different modes:

- **Unencrypted reads:** A ship can publish data into its namespace without encryption. Response messages are signed using the ship's private key. The signature attests to the scry binding: the pair of the scry path and the datum at that path.
- **One-to-One Encrypted Reads:** A ship can make data available to a single peer ship. Response messages are authenticated via external HMAC and internal signature. They are encrypted using a symmetric key derived from the Diffie-Hellman key exchange of the two ships' keys.
- **Commands:** Commands and their acks are both handled as one-to-one encrypted reads.
- **One-to-Many Encryption:** A ship can make data available to many ships by sharing an encryption key for that data to each ship using a one-to-one encrypted read. The requesting ship then uses that key to encrypt the request's scry path and decrypt the scry response.

The core encryption primitives consist of:

- `kdf`: BLAKE3, in its key derivation mode.
- `crypt`: XChaCha8, with its 24-byte nonce derived by processing the (arbitrary-length) input initialization vector (IV) using the key derivation function (`kdf`) with "`mesa-crypt-iv`" as the context string.

Messages and their paths are encrypted separately. First, `kdf` is used to derive an authentication key and encryption key from the shared secret. The authentication key is used to compute a 128-bit keyed BLAKE3 hash of the path; this serves as the Authenticated Encryption with Associated Data (AEAD) tag. The encryption key is then used to encrypt the path with `crypt`, using the tag as the IV. Concatenating the encrypted path and authentication tag yields a "sealed" path. The message itself is then encrypted with `crypt`, using the sealed path as the IV. Authentication of the message is achieved via a Merkle hashing scheme described later.

489 Directed Messaging’s encryption scheme uses a variant of
490 ChaCha20, XChaCha, with reduced rounds for performance.
491 XChaCha is an extended-nonce variant of ChaCha that accepts
492 a 192-bit nonce instead of the standard 96-bit nonce. However,
493 rather than using the caller-provided initialization vector di-
494 rectly as the nonce, Directed Messaging first applies a BLAKE3
495 key derivation function to derive a deterministic 24-byte nonce
496 from the IV using the context string “mesa-crypt-iv”. This
497 XChaCha operation with 8 rounds then produces a derived key
498 and extended nonce, which are subsequently used for the ac-
499 tual ChaCha encryption (also with 8 rounds) of the message
500 payload. The use of 8 rounds instead of the standard 20 is a
501 performance optimization – ChaCha’s security margin allows
502 for this reduction in cryptographic applications where the ex-
503 treme paranoia of 20 rounds may be unnecessary (Aumasson,
504 2019), and the deterministic nonce derivation via BLAKE3 adds
505 an additional layer of domain separation.

506 Because the scry namespace immutably binds paths to their
507 message data, the path serves as a synthetic IV for the message,
508 making encryption deterministic. This solves multiple prob-
509 lems. It (along with other principles of Directed Messaging)
510 prevents replay attacks by construction. Every Directed Mes-
511 saging packet is idempotent at the application level (a dupli-
512 cate packet can trigger a duplicate ack and minor state changes
513 in the runtime and Arvo kernel related to routing state, but it
514 cannot modify anything visible to an application). It further
515 removes the need for explicit nonce management, such as gen-
516 erating, storing, and transmitting an explicit nonce for each
517 message. Not tracking nonces reduces the system’s security
518 attack surface area considerably, since nonce state misman-
519 agement is a common source of vulnerabilities. Finally, sup-
520 porting encrypted values in the namespace allows the system
521 to implement encryption using overlay namespaces (described
522 in more detail below), which provide a clean layering that sep-
523 arates encryption from other concerns.

524 Before transmission, a single 0x1 byte is appended to the
525 encrypted message, called a “trailer byte”. This solves a rep-
526 resentation problem specific to Urbit’s atom system. In Urbit,
527 data is ultimately stored as “atoms”: arbitrary-precision nat-

528 ural numbers. The atom system cannot distinguish between
529 byte streams with equivalent numerical value; that is, it has no
530 way to “say” `0x1000` instead of `0x1` or `0x1000000000` – all are
531 numerically equivalent to `1`.¹ Thus, if a ciphertext happens to
532 end with one or more zero bytes, those would be stripped when
533 the ciphertext is represented as an atom, corrupting the data.
534 Appending a `0x1` byte ensures that the atom representation al-
535 ways preserves the full length of the ciphertext, including any
536 trailing zeros. During decryption, the code verifies that the
537 final byte is indeed `0x1` (which catches truncation or corrup-
538 tion) and then strips it before decrypting. This construction
539 provides authenticated encryption properties through the de-
540 terministic relationship between the IV and nonce, ensuring
541 that any tampering with the ciphertext or IV will result in de-
542 cryption failure.

543 **4.1 Message Authentication and Encryption Details**

544 **4.1.1 Overlay Namespaces**

545 Each of the three privacy modes has its own “overlay names-
546 space”, i. e. a part of the scry namespace that somehow trans-
547 forms values bound to a different part of the namespace. A
548 path in an overlay namespace often consists of a path prefix
549 containing the name of the overlay and any parameters needed
550 for the transformation it performs on the datum at the overlaid
551 path, followed by the overlaid path.

552 A handler function that deals with scry requests to the
553 overlay namespace is free to parse transformation parameters
554 out of the overlay prefix, inspect the overlaid path, make a scry
555 request for the data at that path, make scry requests related to
556 that path (such as existence checks for file paths), and run arbi-
557 trary code to transform the results. This is all possible because
558 scry requests are purely functional by construction – they are
559 deterministic functions of their inputs, with no hidden inputs,
560 and there is no mechanism by which they could change Arvo
561 state.

¹Note the relative most-significant byte (MSB) order notation used here, contrary to Urbit’s customary LSB order.

562 Directed Messaging uses overlay namespaces not only for
563 privacy modes, but also to publish individual packets within a
564 message. The packet's size (expressed as the log base 2 kiB, e.g.
565 3 for 8 kiB or 4 for 15 kiB) and fragment number (index within
566 the message) are parameters to this overlay, which overlays the
567 message's scry path.

568 Directed Messaging is the first Urbit kernel module to make
569 heavy use of overlay namespaces in its design. They play
570 an important role in maintaining boundaries between layers
571 within the system: privacy is separated, by construction, from
572 other concerns due to the isolation imposed by overlay names-
573 spaces. For example, an application can declare what privacy
574 mode it wants to use for a piece of data it publishes, and the
575 kernel enforces that by exposing it over the network using the
576 appropriate overlay namespace.

577 **4.1.2 %publ namespace (unencrypted public)**

578 Authentication: Ed25519 signature only (no encryption)

- 579 1. No encryption: The message data is jammed but not en-
580 crypted. The serialized response is sent in plaintext.
- 581 2. Signature authentication: A 64-byte Ed25519 signature
582 is computed over:
 - 583 • The encoded beam path
 - 584 • The LSS root of the unencrypted jammed data
- 585 3. Publisher's signing key: The signature uses the pub-
586 lisher's Ed25519 private key (extracted from their net-
587 working key).
- 588 4. Verification: The receiver verifies the signature using the
589 publisher's Ed25519 public key retrieved from Azimuth.

590 The %publ namespace uses unencrypted paths with the
591 structure:

592 /publ/[life]/[path]

593 in which `life` (key revision number) of the publisher's net-
594 working keys is used to identify which public key to use for sig-
595 niture verification; and `path` is the actual user path in plaintext.
596 This is not encrypted and is visible to all network observers.

597 Privacy properties:

- 598 • Everything is public: both the publisher's identity/key
599 version and the content path are visible to anyone
600 • No encryption is applied to either the path or the mes-
601 sage payload
602 • Authentication comes solely from the Ed25519 signature,
603 which proves the publisher created this content
604 • Key rotation is supported through the life counter

605 Use cases:

- 606 • Public data that should be readable by anyone
607 • Content where authenticity matters but confidentiality
608 doesn't
609 • Simpler than encrypted namespaces since no key ex-
610 change or group key distribution is required

611 **4.1.3 %shut namespace (group encrypted)**

612 Authentication: Ed25519 signature over encrypted data

- 613 1. Message encryption: The message is encrypted with
614 XChaCha20-8 using a group symmetric key. The key
615 is provided via the `%keen` task (not derived from ECDH).
616 The encrypted path indicates which group key to use.
617 2. Signature authentication: A 64-byte Ed25519 signature
618 is computed over:

619 • The encoded beam path
620 • The LSS root of the encrypted data

621 3. Publisher's signing key: The signature uses the pub-
622 lisher's Ed25519 private key, proving the publisher cre-
623 ated this encrypted payload.

- 624 4. Verification: The receiver verifies the signature using the
625 publisher's Ed25519 public key from Azimuth, then de-
626 crypts with the group key.
627 5. Security model: Signature proves authenticity from the
628 publisher; encryption provides confidentiality to group
629 members. Anyone with the group key can decrypt, but
630 only the publisher can create valid signatures.

631 The %shut namespace uses encrypted paths with the struc-
632 ture:

633 /shut/[key-id]/[encrypted-path]

634 Components:

- 635 1. key-id: A numeric identifier indicating which group
636 symmetric key to use for decryption. This allows mul-
637 tiple groups to be supported, each with their own key.
- 638 2. encrypted-path: The actual user path, encrypted using
639 the group key. This is sealed with the same symmetric
640 key used to encrypt the message payload, making the
641 entire scry path opaque to anyone without the group key.

642 Privacy properties:

- 643 • The actual content path is hidden from network ob-
644 servers and unauthorized parties
- 645 • Only the key ID is visible in plaintext.
- 646 • The group key must be obtained separately (typically via
647 a %keen to decrypt both the path and the message pay-
648 load).
- 649 • Different groups using different key IDs can coexist
650 without revealing which content is being accessed.

651 **4.1.4 %chum namespace (1-to-1 encrypted)**

652 Authentication: HMAC only (no signatures)

- 653 1. Message encryption: The message is encrypted with
654 XChaCha20-8 using a symmetric key derived from
655 Curve25519 ECDH key exchange between the two ships'
656 networking keys.

- 657 2. HMAC authentication: A 16-byte HMAC (BLAKE3 keyed
658 hash) is computed over:
659 • The encoded beam path.
660 • The LSS root of the encrypted data.
661 3. Shared symmetric key: Both HMAC computation and
662 encryption use the same ECDH-derived symmetric key.
663 Both parties can independently derive this key from their
664 own private key and the other party's public key.
665 4. Verification: The receiver verifies the HMAC using the
666 shared symmetric key, then decrypts with the same key.
667 5. Security model: The HMAC proves the sender pos-
668 sses the shared symmetric key (implicitly authenticat-
669 ing them as the expected peer). No signatures are needed
670 since only two parties share this key. This applies to both
671 pokes and acks.

672 The %chum namespace uses encrypted paths with the struc-
673 ture:

674 /chum/[server-life]/[client-ship]/[client-life]/[encrypted-path]

675 Components:

- 676 1. server-life: The life (key revision number) of the server
677 ship's networking keys, used to identify which version
678 of their keys to use for ECDH key derivation.
- 679 2. client-ship: The @p address of the client ship in the com-
680 munication pair.
- 681 3. client-life: The life of the client ship's networking keys,
682 used to identify which version of their keys to use for
683 ECDH key derivation.
- 684 4. encrypted-path: The actual user path, encrypted using
685 the symmetric ECDH key derived from both ships' net-
686 working keys. This makes the scry path opaque to net-
687 work observers.

688 Privacy properties:

- 689 • The actual content path is hidden from network ob-
690 servers.
- 691 • The identities of both parties and their key versions are
692 visible in plaintext.
- 693 • Only the two ships involved can derive the symmetric
694 key to decrypt the path and payload.
- 695 • Key rotation is supported through the life counters.

696 **4.1.5 Other Cryptographic Properties**

697 Directed Messaging relies on the ability to rotate keys on chain
698 for its forward secrecy. Future versions of the protocol might
699 add a ratchet to minimize the damage if a private key is com-
700 promised.

701 **4.2 Packet Authentication**

702 TODO: more closely match the tone of the rest of this docu-
703 ment TODO: more diagrams, clearer explanation of Lackman
704 traversal

705 One of the goals of Directed Messaging was to improve
706 upon the safe-but-dumb “sign every 1 KiB packet” design of
707 old %ames. The standard approach is to use asymmetric crypto
708 to establish a shared AEAD key, and use it to authenticate each
709 packet. This is just as safe as signing every packet, and orders
710 of magnitude faster. However, we still can’t verify that a peer
711 is sending us *correct* data until we’ve received the entire mes-
712 sage. They could send us 999 good packets and one bad one,
713 and we’d have no way of knowing which was which. This is
714 especially annoying if we want to download in parallel from
715 multiple peers: if the final result is invalid, which peer is to
716 blame? If we want to solve this problem, we need to get a little
717 more bespoke.

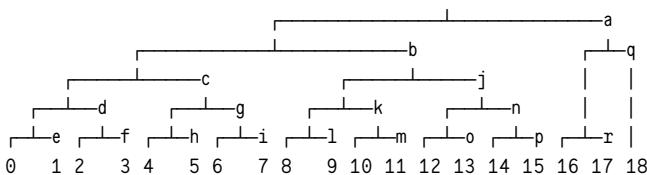

718 Verifying that a packet belongs to a particular message is
719 a job for a Merkle tree. So our protocol needs to split mes-
720 sage data into the leaves of a tree, and send both leaf data and

tree hashes. Early on, we debated whether to make these distinct request types; we settled on interleaving them. Now the question becomes: which tree hashes do you need to send, and when do you send them?

Our relevant design constraints were as follows:

- Sufficiently-small messages should not require more than one packet.
- It should be possible to download in parallel.
- The protocol should be flexible with respect to the size of a leaf.

An obvious first place to look for inspiration was Bao. However, Bao is not very amenable to being split into fixed-size packets: it intermingles leaf data and tree hashes into one stream, and the number of consecutive hashes varies based on the offset. You could modify it such that each packet consists of a leaf followed by at most one hash; indeed, this was the initial plan. Visually:

This is a binary numeral tree: a structure composed of perfect binary trees, imposed upon a flat sequence of bytes. The numbers 0-18 represent leaf data (typically 1 KiB per leaf), while letters *a*-*r* represents tree hashes that are used to verify the leaves. So packet 3 would contain bytes 3072-4096 and leaf hash *d*.

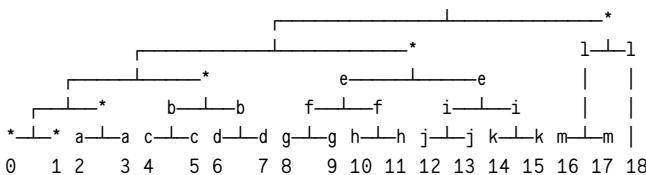

The main problem with this approach is that it requires buffering. In order to verify leaf *o*, we need hashes *a* through *e* – five packets! Worse, once we've received five packets, we have the whole [0, 4) subtree, making hashes *d* and *e* redundant. (In BNTs, we use the notation [n, m) to refer to the perfect subtree containing leaves *n* through *m*-1.)

750 Buffering a few packets is not the end of the world, but the
 751 whole thing had kind of a bad smell to it. We asked: what
 752 would happen if we added another constraint?

- 753 • It should be possible to validate each packet as soon as it
 754 arrives, with no buffering.

755 For starters, an inescapable consequence of this constraint
 756 is that we must send the *full* Merkle proof for the first leaf
 757 before we can send the leaf data itself. Also, we can no longer
 758 send hashes that can't be immediately verified. For example, to
 759 verify g , we first need to have verified c ; we can then combine
 760 g with its sibling hash and confirm that the result matches c .

761 While adding another constraint seems like it would make
 762 our life harder, in reality the opposite happened: the proto-
 763 col was greatly simplified. It turns out that by front-loading
 764 the initial proof hashes, we ensure that the received leaf data
 765 and hashes will never “run ahead” of what can be immediately
 766 verified. Here’s what it looks like in practice:

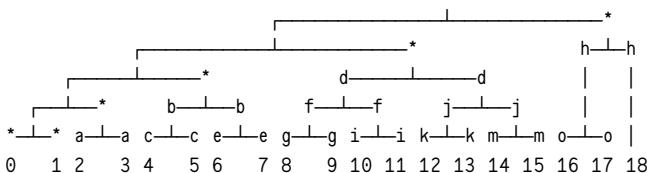

767 In the initial packet, we send the Merkle proof for leaf 0,
 768 i.e. all of the hashes marked with *. Each subsequent packet
 769 contains leaf data (leaf 0, 1, 2, etc.), and possibly a “pair” (a, b ,
 770 c , etc.), which comprises *both* child hashes under a particular
 771 node. Packet-by-packet, the verifier sees:

- 772 Packet 0: Signed Merkle root + Merkle proof for leaf 0.
 773 Verify proof against signed root.
 774 We now have [0,1], [1,2], [2,4], [4,8], [8,16],
 775 and [16,19].
- 776 Packet 1: Leaf 0 + Pair a.
 777 Verify leaf 0 against [0,1].
 778 Verify pair a against [2,4].
 779 We now have [1,2], [2,3], [3,4], [4,8], [8,16],
 780 and [16,19].

```
781 Packet 2: Leaf 1 + Pair b.  
782     Verify leaf 1 against [1,2).  
783     Verify pair b against [4,8).  
784     We now have [2,3), [3,4), [4,6), [6,8), [8,16),  
785     and [16,19).  
786 Packet 3: Leaf 2 + Pair c.  
787     Verify leaf 2 against [2,3).  
788     Verify pair c against [4,6).  
789     We now have [3,4), [4,5), [5,6), [6,8), [8,16),  
790     and [16,19).  
791 ... and so on.
```

792 At each step, we “consume” two hashes (one to verify a leaf,
793 one to verify a pair), and add the pair to our verified set; thus,
794 the number of verified-but-unused hashes stays constant until
795 we get to packet 13. At this point, packets still contain leaf data
796 (so we’ll consume one hash), but there are no more pairs left to
797 send; thus, our stockpile of hashes is steadily exhausted, until
798 we consume the final hash to verify the final packet.

799 This is a solid improvement! We dubbed it “Lockstep
800 Streaming,” after the fact that verification proceeds in lockstep
801 with packet receipt. But when we sat down to write the code
802 for matching verified-but-unused hashes to incoming leaves
803 and pairs, things got hairy. It was clearly *possible*, but the ug-
804 liness of the logic suggested that there was a better way. And
805 after filling plenty of notebook pages with hand-drawn Merkle
806 trees, [~rovnyz-ricfer](#) found it: a mapping of packet numbers
807 to hash pairs that was not only much cleaner, but also *scale invariant*. It’s called Blackman ordering, and it looks like this:

809 See the difference? Instead of ordering the pairs on a first-
810 needed basis, we jump around a bit. Specifically, we send a pair
811 whose “height” corresponds to the number of trailing zeroes in
812 the binary representation of the packet number. For example,

813 packet 4 is 100 in binary, with two trailing zeroes, so we send
814 pair d, which sits two levels above the leaves. (As you might
815 expect, the logic gets slightly less clean when the number of
816 leaves is not a power of two, but it's not the end of the world.)
817 an Packet-by-packet verification for Blackman ordering:

818 The $[x, y)$ notation indicates a half-open set, i. e. it includes
819 $x, x+1, x+2, \dots, y-1$. $[2, 4)$ contains elements 2 and 3.
820 $[0, 1)$ contains the single element 0.

821 Packet 0: Signed Merkle root + Merkle proof for leaf 0.

822 Verify proof against signed root.

823 We now have $[0, 1)$, $[1, 2)$, $[2, 4)$, $[4, 8)$, $[8, 16)$,
824 and $[16, 19)$.

825 Packet 1: Leaf 0 + Pair a.

826 Verify leaf 0 against $[0, 1)$.

827 Verify pair a against $[2, 4)$.

828 We now have $[1, 2)$, $[2, 3)$, $[3, 4)$, $[4, 8)$, $[8, 16)$,
829 and $[16, 19)$.

830 Packet 2: Leaf 1 + Pair b.

831 Verify leaf 1 against $[1, 2)$.

832 Verify pair b against $[4, 8)$.

833 We now have $[2, 3)$, $[3, 4)$, $[4, 6)$, $[6, 8)$, $[8, 16)$,
834 and $[16, 19)$.

835 Packet 3: Leaf 2 + Pair c.

836 Verify leaf 2 against $[2, 3)$.

837 Verify pair c against $[4, 6)$.

838 We now have $[3, 4)$, $[4, 5)$, $[5, 6)$, $[6, 8)$, $[8, 16)$,
839 and $[16, 19)$.

840 ... and so on.

841 Shortly after, ~watter-parter tweaked the ordering
842 slightly, offsetting it by one; this further simplified the low-
843 level bithacking. We called this variant “Lackman ordering,”
844 and it’s what we used in the final version of Lockstep Stream-
845 ing.

846 Packet-by-packet verification for Lackman ordering:

847 Packet 0: Signed Merkle root + Merkle proof for leaf 0.

848 Verify proof against signed root.

849 We now have $[0, 1)$, $[1, 2)$, $[2, 4)$, $[4, 8)$, $[8, 16)$,
850 and $[16, 19)$.

851 Packet 1: Leaf 0 (no pair).

852 Verify leaf 0 against $[0, 1)$.

```
853           We now have [1,2), [2,4), [4,8), [8,16), and
854           [16,19).
855   Packet 2: Leaf 1 + Pair a.
856       Verify leaf 1 against [1,2).
857       Verify pair a against [2,4).
858       We now have [2,3), [3,4), [4,8), [8,16), and
859           [16,19).
860   Packet 3: Leaf 2 + Pair b.
861       Verify leaf 2 against [2,3).
862       Verify pair b against [4,8).
863       We now have [3,4), [4,6), [6,8), [8,16), and
864           [16,19).
865   ... and so on.
```

866 Compared to Blackman ordering, the pairs appear offset by
867 one position, which simplifies the bit-manipulation logic for
868 computing which pair to include in each packet.

869 There's one more optimization worth mentioning: If the
870 message is small enough, we can skip the initial step of sending
871 a packet containing only a Merkle proof (with no leaf data).
872 Obviously, for a one-leaf message, we can simply send that leaf;
873 the hash of that leaf is the Merkle root. For a two-leaf message,
874 we can send the leaf plus its sibling hash ([1,2)); the verifier
875 can hash the first leaf and combine it with the sibling hash to
876 recover the root. And for a three- or four-leaf message, we can
877 send [1,2) and [2,3) (or [2,4), respectively). That's the limit,
878 though; if a message has five leaves, we would need to send at
879 least three sibling hashes for the verifier to recompute the root,
880 but our packet framing only allows up to two hashes.

881 4.2.1 Arena Allocator

882 Directed Messaging uses a simple bump allocator arena for
883 memory management. Each arena is a contiguous block of
884 memory with three pointers: the start of the allocation (`dat`),
885 the current allocation position (`beg`), and the end of the block
886 (`end`). The `new()` macro allocates objects by advancing the `beg`
887 pointer with proper alignment.

888 The arena allocator provides *no individual deallocation* –
889 once memory is allocated from an arena, it can't be freed sepa-

890 rately. Instead, the entire arena is freed at once when the data
891 structure that owns it is destroyed.

892 **Allocation Patterns** Arenas are created with sizes tai-
893 lored to their use case:

- 894 • **Pending Interest Table entries** use 16 KiB arenas.
895 These store lane addresses for pending requests, with the
896 arena holding the entry itself plus a linked list of address
897 records.
- 898 • **Pending requests** allocate arenas at **5× the expected**
899 **message size**. A request receiving a 1 MiB message gets
900 a 5 MiB arena. This single arena holds the request state,
901 fragment data buffer, LSS authentication pairs, packet
902 statistics, bitset tracking received fragments, and pre-
903 serialized request packets.
- 904 • **Jumbo frame cache entries** allocate based on proof
905 size, data size, hash pairs, plus a 2KB buffer. For a 1 MiB
906 message, this might be around 1–2 MiB. The arena stores
907 the cached response data, Merkle proof spine, and au-
908 thentication hashes.
- 909 • **Temporary arenas** for packet sending use message size
910 plus 16 KB to hold serialized packets plus overhead.
- 911 • **Scry callbacks** get small arenas for asynchronous Arvo
912 interactions.

913 **Deallocation Triggers** Arenas are freed only when
914 their parent data structure is destroyed:

- 915 • **Request completion:** When all fragments arrive, the
916 request is deleted and its arena freed. This happens asyn-
917 chronously through libuv's handle cleanup to ensure
918 proper timer shutdown before freeing memory.
- 919 • **Authentication failure:** If LSS verification fails while
920 processing fragments, the entire request is immediately
921 deleted.

- **Timeout expiration:** When retry timers exhaust their attempts, the request is deleted.
- **PIT expiration:** After 20 seconds, entries are cleaned from the Pending Interest Table.
- **Cache eviction:** When the jumbo cache exceeds 200 MiB, it's entirely cleared and all cached arenas are freed.

Lifecycle A typical request lifecycle:

1. **Allocation:** Receive initial packet, create arena with 5× data size, allocate all request state from arena.
2. **Growth:** As fragments arrive, write into pre-allocated buffers within the arena.
3. **Completion:** All fragments received, construct final message, send to Arvo.
4. **Cleanup:** Delete request from map, stop timer, close handle asynchronously.
5. **Deallocation:** In UV callback, free entire arena with single call.

This design trades memory efficiency for speed. Arenas may hold unused space, but allocation is extremely fast (just pointer arithmetic), and the single-free design eliminates per-object deallocation overhead and fragmentation issues.

4.2.2 Download Checkpointing

This has not been deployed to the network, but this design allows the requesting ship's runtime to inject jumbo frames of arbitrary size into its Arvo as each one finishes downloading, with real authentication by using Lockstep. Arvo will seamlessly store those jumbo frames and accumulate them until it has the whole message, at which time it will deserialize the message into an Urbit 'noun' data structure and deliver it to the application or kernel module that had triggered the request.

953 This allows the system to make effective use of Arvo as a
954 download checkpointing system. After a process crash, ma-
955 chine restart, or any other transient failure, the download can
956 be resumed with minimal loss of information.

957 Injecting an authenticated jumbo frame into Arvo main-
958 tains a security boundary. Urbit's main runtime, Vere, has two
959 Unix processes: one runs the Arvo kernel, and the other han-
960 dles input and output. Arvo maintains ultimate responsibility
961 for cryptographic operations. This lets the private key remain
962 solely in the Arvo process, leaving the I/O process without the
963 ability to encrypt, decrypt, authenticate, or verify authentica-
964 tion.

965 Instead, the runtime delegates any operation requiring a
966 private key to Arvo, including validating the message-level au-
967 thentication in the first packet of a scry response. To add a
968 layer of defense in depth in case the I/O process is compro-
969 mised, Arvo performs its own packet validation, including the
970 Lockstep packet authentication. This remains efficient because
971 each packet can be a large jumbo frame.

972 Checkpointing has another benefit. No matter how large a
973 message is, the downloader can keep a fixed upper bound on
974 the memory footprint while download that message, propor-
975 tional to one jumbo frame.

976 4.2.3 Download Resumption

977 After a transient failure – most commonly a process crash or
978 machine restart – a requesting ship can resume a download.
979 In order to pick up from where it left off, the runtime first
980 asks its local Arvo for the leaf-packet hashes it needs, which
981 Arvo generates on demand from the jumbo frames that have al-
982 ready been downloaded and stored in Arvo. This is $O(\log(n))$
983 hashes, where n is the message length, and no message data
984 needs to be sent over inter-process communication in order to
985 resume a download, preventing restarts from becoming slow
986 and memory-intensive.

987 Once the runtime has the hashes it needs, it resumes the
988 Lockstep streaming verification that it had been doing, begin-
989 ning with the next jumbo frame after the last one that had been

990 downloaded and saved in Arvo.

991 Download checkpointing and resumption together provide
992 a good set of tools for download management. This is beyond
993 what TCP provides, or even HTTP. HTTP has resumption head-
994 ers, but both client and server have to opt into using them, so
995 in practice many HTTP-based downloads cannot be resumed.

996 5 Congestion Control

997 In Directed Messaging, congestion control is pluggable. The re-
998 questing ship decides how many request packets to send and at
999 what time. The publisher ship is only responsible for respond-
1000 ing to requests and does not participate in congestion control.

1001 It is possible for an Urbit implementation to have function-
1002 ing, if not performant, networking, without any runtime im-
1003 plementation of congestion control. The formal specification
1004 in the networking module of the Arvo kernel for how a ship
1005 sends request packets is a simple one-at-a-time indefinite re-
1006 peating timer. The ship sends the first request packet, repeat-
1007 ing it every thirty seconds until a response packet is heard, at
1008 which point it begins requesting the next packet.

1009 Performant congestion control, then, is an extension of Ur-
1010 bit's idea of a "jet", i. e. a peephole optimization that replaces
1011 a built-in function, defined formally but is likely slow, with an
1012 optimized low-level implementation.

1013 In practice, this slow packet re-send is used for retrying
1014 dead connections, where the publishing ship has been unre-
1015 sponsive for a long time. This is important because Urbit net-
1016 work requests generally do not time out at the application
1017 level; they are considered persistent, and they must be retried
1018 indefinitely. Fast, runtime-based congestion control only kicks
1019 in when the runtime receives a response packet, indicating the
1020 publishing ship has become responsive.

1021 The current implementation of Directed Messaging em-
1022 ploys a modified TCP Tahoe-style congestion control algo-
1023 rithm adapted to its request/response architecture and packet-
1024 oriented nature. The protocol's congestion control differs from
1025 traditional TCP in several fundamental ways due to its pull-

1026 based communication model and implicit acknowledgment
1027 scheme.

1028 **5.1 Architectural Foundation**

1029 Unlike TCP’s push-based model where senders transmit data
1030 and await separate acknowledgment packets, Directed Mes-
1031 saging operates on a request/response paradigm. The request-
1032 ing ship sends `PEEK` packets to solicit specific fragments, and
1033 the responding ship sends `PAGE` packets containing the re-
1034 quired data. The arrival of each `PAGE` packet serves as an im-
1035 plicit acknowledgment—no separate `ACK` packets exist in the
1036 protocol. This inversion places congestion control responsibil-
1037 ity on the requester rather than the sender, allowing the party
1038 pulling data to directly regulate network load.

1039 The protocol operates on fixed-size fragments rather than
1040 byte streams. Each fragment contains up to 1024 bytes of pay-
1041 load data (at the default `$bloq` parameter of 13). The con-
1042 gestion window (`cwnd`) measures capacity in fragment count
1043 rather than bytes, providing coarser but simpler granularity
1044 than TCP’s byte-oriented approach.

1045 **5.2 State Variables**

1046 Congestion control state is maintained per peer and includes:

- 1047 • `cwnd` (congestion window): Number of fragments al-
1048 lowed in flight simultaneously.
- 1049 • `ssthresh` (slow start threshold): Boundary between ex-
1050 ponential and linear growth phases.
- 1051 • `rttvar` (RTT variance): Smoothed variance in round-trip
1052 measurements.
- 1053 • `rto` (retransmission timeout): Calculated timeout for loss
1054 detection.

1055 Per-request state tracks which fragments have been sent, when
1056 they were sent, how many retransmission attempts have oc-
1057 curred, and which fragments have been received using an effi-
1058 cient bitset representation.

1059 5.3 Slow Start and Congestion Avoidance

1060 The protocol implements two growth phases analogous to TCP:

- 1061 • **Slow Start Phase** ($cwnd < ssthresh$): Upon initiating a
1062 request or recovering from congestion, $cwnd$ begins at 1
1063 fragment. For each fragment acknowledgment received
1064 (implicitly, by receiving the corresponding PAGE packet),
1065 $cwnd$ increments by 1. This produces exponential growth:
1066 $1 \rightarrow 2 \rightarrow 4 \rightarrow 8 \rightarrow 16$, allowing rapid probing of available
1067 bandwidth.
- 1068 • **Congestion Avoidance Phase** ($cwnd \geq ssthresh$): Once
1069 $cwnd$ reaches $ssthresh$, growth becomes linear.
1070 The implementation uses a fractional accumulation
1071 strategy: for each acknowledgment, a fractional counter
1072 accumulates $1/cwnd$ of a window increment. When
1073 the accumulated value reaches $cwnd$, the actual $cwnd$
1074 increments by 1, yielding approximately one window
1075 size increase per round-trip time.

1076 The default $ssthresh$ is initialized to 10,000 fragments (approx-
1077 imately 10 MB), effectively allowing slow start to dominate for
1078 typical transfer sizes.

1079 5.4 Loss Detection and Recovery

1080 Directed Messaging currently implements timeout-based loss
1081 detection only, without fast retransmit or fast recovery mech-
1082 anisms. This places it closest to TCP Tahoe's behavior, though
1083 with an important modification to timeout handling.

- 1084 • **Timeout Detection:** Each in-flight fragment's trans-
1085 mission time is recorded. A retransmission timer fires
1086 when the oldest unacknowledged fragment exceeds the
1087 calculated RTO. The protocol scans all in-flight fragments
1088 upon timeout and retransmits any that have been out-
1089 standing beyond the RTO interval.
- 1090 • **Timeout Response:** Upon detecting packet loss via
1091 timeout, the protocol reduces network load by:

- 1092 1. Setting `ssthresh = max(1, cwnd / 2)`.
1093 2. Setting `cwnd = ssthresh`.
1094 3. Doubling `rto` (up to a maximum bound).

1095 This differs from TCP Tahoe, which sets `cwnd = 1` and restarts
1096 slow start from the beginning. Directed Messaging's approach
1097 is less conservative, immediately resuming transmission at the
1098 reduced threshold rather than slowly ramping up from a single
1099 packet. This assumes that while congestion occurred, the net-
1100 work can still sustain traffic at half the previous rate without
1101 requiring a full slow start restart.

1102 The lack of fast retransmit (triggering on three duplicate ac-
1103 knowledgments) represents a significant difference from mod-
1104 ern TCP variants. Fast retransmit requires detecting duplicate
1105 acks, which in Directed Messaging would mean detecting re-
1106 quests for the same fragment. However, the current implemen-
1107 tation treats each arriving PAGE packet independently without
1108 tracking the ordering implications that would enable fast re-
1109 transmit. This is a known simplification intended for future
1110 enhancement.

1111 **5.5 Round-Trip Time Estimation**

1112 The protocol employs Jacobson/Karels RTT estimation, the
1113 same algorithm used in TCP. When a fragment acknowledg-
1114 ment arrives (excluding retransmissions), the round-trip time
1115 measurement (`rtt_datum`) is calculated as the difference be-
1116 between current time and transmission time.

1117 RTT smoothing uses exponential weighted moving aver-
1118 ages with traditional TCP parameters:

- 1119 • $\text{rtt} = (\text{rtt_datum} + 7 \cdot \text{rtt}) / 8$, $\alpha = 1/8$.
1120 • $\text{rttvar} = (|\text{rtt_datum} - \text{rtt}| + 7 \cdot \text{rttvar}) / 8$, $\beta = 1/4$.
1121 • $\text{rto} = \text{rtt} + 4 \cdot \text{rttvar}$.

1122 The retransmission timeout `rto` is furthermore clamped to a
1123 minimum of 200 milliseconds and a maximum that varies by

1124 context (typically 2 minutes for most traffic, 25 seconds for
1125 keepalive probes to sponsors).

1126 Retransmitted fragments do not contribute to RTT esti-
1127 mation, following Karn's algorithm to avoid ambiguity about
1128 which transmission is being acknowledged.

1129 5.6 Selective Request Architecture

1130 The implicit acknowledgment scheme combines naturally with
1131 selective fragment requesting. The protocol maintains a bitset
1132 tracking which fragments have been received. When request-
1133 ing additional fragments during congestion-controlled trans-
1134 mission, the requester consults both the congestion window
1135 (how many new requests can be sent) and the bitset (which
1136 fragments are needed). This provides the benefits of TCP SACK
1137 without requiring additional protocol machinery – selectivity
1138 is inherent to the request/response model.

1139 When fragments arrive out of order, the LSS (Lockstep Sig-
1140 nature Scheme) authentication requires buffering misordered
1141 packets until their Merkle proof predecessors arrive. Once au-
1142 thenticated, these fragments are marked received in the bitset,
1143 and the congestion control state updates accordingly.

1144 5.7 Request Rate Limiting

1145 The congestion window limits the number of PEEK requests
1146 in flight. Before sending additional requests, the protocol
1147 calculates

1148 `available_window = cwnd - outstanding_requests`
1149 where `outstanding_requests` counts fragments that have been
1150 requested but not yet received. This naturally throt-
1151 tles the request rate according to observed network capac-
1152 ity. As PAGE packets arrive (serving as acknowledgments),
1153 `outstanding_requests` decreases, allowing new PEEK packets to
1154 be sent.

1155 This pull-based flow control provides inherent advantages:
1156 the requester cannot be overwhelmed by data it didn't request,
1157 and the congestion control directly limits the rate at which the
1158 requester pulls data from the network.

1159 5.8 Per-Peer State Management

1160 Congestion control state is maintained per peer rather than per
1161 connection or per flow. All concurrent requests to the same
1162 peer share a single congestion window and RTT estimate. This
1163 design choice reflects the architectural principle that network
1164 capacity constraints exist between pairs of ships rather than
1165 between individual conversations.

1166 Sharing state across requests to the same peer provides sev-
1167 eral benefits:

- 1168 1. RTT measurements from any request improve estimates
1169 for all requests.
- 1170 2. Congestion signals from one request protect other con-
1171 current requests.
- 1172 3. State initialization costs are amortized across multiple
1173 requests.
- 1174 4. The aggregate transmission rate to each peer is con-
1175 trolled.

1176 However, this also means that multiple concurrent large trans-
1177 fers to the same peer must share available bandwidth, which
1178 could reduce throughput compared to per-flow windows in
1179 some scenarios.

1180 5.9 Initial Window and Probing

1181 New peer connections begin with conservative initial values:
1182 $cwnd = 1$, $rtt = 1000 \text{ ms}$, $rttvar = 1000 \text{ ms}$, $rto = 200 \text{ ms}$. The
1183 first fragment request initiates RTT measurement and slow
1184 start growth. This cautious initialization ensures the protocol
1185 probes network capacity gradually rather than assuming high
1186 bandwidth is available.

1187 For peers with no recent traffic, the congestion state per-
1188 sists but becomes stale. Future enhancements may include
1189 state expiration and re-initialization after prolonged idle pe-
1190 riods, though the current implementation maintains state in-
1191 definitely once a peer is known.

1192 **5.10 Comparison with TCP Variants**

1193 The congestion control algorithm most closely resembles TCP
1194 Tahoe but with notable differences:

1195 Similarities to Tahoe:

- 1196 • Slow start with exponential growth
1197 • Congestion avoidance with linear growth
1198 • Loss detection via timeout only
1199 • Conservative initial probing

1200 Differences from Tahoe:

- 1201 • Modified timeout recovery (`cwnd = ssthresh` rather than
1202 `cwnd = 1`)
1203 • Packet-oriented rather than byte-oriented windows
1204 • Implicit acknowledgment via data receipt
1205 • Pull-based rather than push-based architecture
1206 • Per-peer rather than per-connection state

1207 Compared to NewReno/SACK, the protocol lacks fast re-
1208 transmit and fast recovery, making it less responsive to iso-
1209 lated packet loss. However, the selective request architecture
1210 provides the functional benefits of SACK naturally. The implicit
1211 acknowledgment scheme eliminates issues with ACK loss and
1212 compression that affect TCP.

1213 **5.11 Design Trade-offs**

1214 The congestion control design reflects several architectural
1215 trade-offs. Advantages include:

- 1216 • Simpler than modern TCP variants (no fast recovery com-
1217 plexity).
1218 • Natural selective acknowledgment through request/re-
1219 sponse model.

- 1220 • Requester controls rate, preventing receiver overwhelm.
- 1221 • No separate ACK channel to fail.
- 1222 • Precise retransmission control with bitset tracking.

1223 The limitations include:

- 1224 • Lack of fast retransmit increases latency for isolated
1225 losses.
- 1226 • Packet-oriented windows provide coarser bandwidth
1227 control.
- 1228 • Per-peer state sharing may reduce throughput for con-
1229 current flows.
- 1230 • Modified timeout behavior is less studied than standard
1231 algorithms.

1232 5.12 Future Enhancements

1233 The protocol architecture supports several potential improve-
1234 ments without fundamental redesign. Fast retransmit could be
1235 implemented by tracking fragment request patterns and de-
1236 tecting when requests skip over missing fragments. Fast re-
1237 cover could leverage the existing `ssthresh` calculation while
1238 avoiding the full slow start restart. Additional sophistication
1239 in RTT measurement could distinguish network delay from ap-
1240 plication processing time.

1241 The current implementation represents a pragmatic bal-
1242 ance between simplicity and effectiveness, providing reason-
1243 able congestion control while keeping the protocol accessible
1244 to implementation and formal verification.

1245 6 Integration

1246 In order to deploy Directed Messaing to Urbit's live network,
1247 the previous version of the protocol needed to remain opera-
1248 tional, since there is no central authority that can force Urbit

1249 ships to update to a particular version. The authors decided
1250 further that each ship should be able to upgrade connections
1251 to peer ships one by one and be able to downgrade it without
1252 data loss.

1253 This was possible due to the persistent, transactional nature
1254 of both the previous and new versions of the protocol.

1255 6.1 Ames Flows

1256 The Arvo kernel has a concept of an Ames “flow”, a directed
1257 connection between ships where the subscriber ship can send
1258 commands and the publisher ship can send responses, both as
1259 “commands” at the level of Directed Messaging.

1260 The implementation of Directed Messaging maintained the
1261 interface to the rest of the system, without modification. Ap-
1262 plications do not need to modify their code at all to make use
1263 of Directed Messaging.

1264 7 Future Work

1265 TODO not sure what to include here @TED why don't we drop
1266 this section and work anything else into the main body and
1267 anything speculative into a conclusion?

- 1268 • star relaying
- 1269 • star scry caching
- 1270 • download checkpointing and resumption
- 1271 • add fast retransmit to congestion control

1272 speculative: - add %pine - add sticky scry Those together
1273 would flesh out a full pub-sub system with stateless publishers
1274 ☈
